Abstract

Objective: To disentangle, among the structural damage observed in Korsakoff's syndrome (KS), those related to alcoholism, and therefore shared between AL and KS, from those specific to KS.

Methods: Magnetic resonance imaging (MRI) data were collected in 11 alcoholic patients with KS, 34 non-Korsakoff alcoholic patients (AL) and 25 healthy control subjects (CS). Gray and white matter volumes were compared in the three groups using a voxel-based approach.

Results: A conjunction analysis indicated a large pattern of shared gray and white matter volume deficits in AL and KS. There were graded effects of volume deficits (KS < AL < CS) in the medial portion of the thalamus, hypothalamus (mammillary bodies), left insula and genu of the corpus callosum. Abnormalities in the left thalamic radiation were observed only in KS.

Conclusions: Our results indicate considerable similarities in the pattern of gray and white matter damage in AL and KS. This finding confirms the widespread neurotoxic effect of chronic alcohol consumption. Only a few cerebral regions, including the medial thalamus, mammillary bodies and corpus callosum, were more severely damaged in KS than in AL. The continuum of macrostructural damage from AL to KS is therefore restricted to key brain structures. Longitudinal investigations are required to determine whether AL with medial thalamic volumes that are comparable to those of KS are at increased risk to develop Korsakoff's syndrome.

Introduction

Korsakoff's syndrome (KS) is characterized by a disproportionate impairment of episodic memory compared with other aspects of cognitive function (1). It results from the combination of heavy alcohol consumption and thiamine deficiency.

Macrostructural abnormalities were initially examined by neuropathological studies, which concluded that specific thalamic nuclei and mammillary bodies play a key role in the pathophysiology of KS (2, 3). In vivo neuroimaging investigations confirmed reduced volume in thalamic and mammillary bodies in KS (4, 5) and revealed widespread cerebral damage with the nodes and connections of the fronto-cerebellar and limbic circuits being especially affected (6). These circuits are also classically described as damaged in non-Korsakoff alcoholics (AL; (7)). A direct comparison of brain damage in KS and AL was conducted in several regions of interest and revealed a continuum of brain damage, from mild in AL to moderate or severe in KS, notably in the mammillary bodies and thalamus (8). However, the comparison between AL and KS has never been conducted throughout the whole brain. The goal of the present study was thus to compare gray and white matter abnormalities in patients with AL and KS using a voxelwise approach to disentangle brain damage related to chronic alcohol consumption, and therefore shared between AL and KS, from those selectively damaged in KS.

Method

Sample

Eleven patients with KS (5 women, age = 56.00 ± 10.55), 34 patients with AL (6 women, age = 43.47 ± 8.36) and 25 healthy control subjects (CS, 14 women, age = 43.88 ± 11.24) were enrolled. None of the participants were taking psychotropic

medication, or presented with history of psychiatric or medical problems (head injury, coma, epilepsy, depression, hepatic encephalopathy etc.), which might affect cognitive function. KS patients were older than AL and controls ($F = 7.37$, $p = 0.001$; Tukey's test: $KS > controls$, $p = 0.003$ and $KS > AL$, $p = 0.001$).

KS patients were diagnosed with reference to the DSM IV criteria for "Persisting Amnesic Disorder". A detailed neuropsychological examination confirmed that all KS presented disproportionately severe episodic memory disorders compared with other cognitive functions (see (6) for more details). All KS patients had a history of heavy drinking but it was difficult to gain an accurate picture of their drinking history because of the amnesia.

AL patients were recruited by clinicians on the basis of the DSM-IV criteria for alcohol dependence while they were receiving treatment for alcohol dependence as inpatients at Caen University Hospital (see (9) for more details). All patients were at an early stage of abstinence (12.67 ± 6.94 days of sobriety prior to inclusion). They were interviewed to specify the length of time they had drunk to excess (16.09 ± 10.29 years) and their usual daily alcohol consumption (23.36 ± 15.01 "standard drinks" per day, i.e. any drink that contains approximately 10 grams of pure alcohol).

Controls were social drinkers as defined by the National Institute on Alcohol Abuse and Alcoholism.

Standard Protocol Approvals, Registrations, and Patient Consents

The participants gave their informed consent prior to their inclusion in the study, which was conducted in line with the Declaration of Helsinki and was approved by the local ethical committee for human investigations.

MRI acquisition and preprocessing

For each subject, a high-resolution T1-weighted volume MRI scan was obtained, which consisted of a set of 128 adjacent axial slices parallel to the AC-PC line, covering the whole brain and with a 1.5-mm slice thickness and a 0.94x0.94 mm pixel size, through the use of the spoiled gradient echo sequence (TR = 10.3 ms; TE = 2.1 ms; FOV = 240x180 mm²; matrix = 256x192). All the MRI datasets were acquired on the same scanner (1.5T Signa Advantage EchoSpeed; General Electric), and based on the same acquisition protocol.

The MRI data were analyzed according to the VBM5 toolbox implemented in Statistical Parametric Mapping 5 software (SPM5; Wellcome department of cognitive Neurology, Institute of Neurology, London, England). Briefly, the procedure included segmentation, registration (spatial normalization) of original MRI datasets using the default MNI template of SPM5 as priors, modulation (to correct only for non-linear warping so that values in the resultant images are expressed as volume corrected for global brain size) and smooth (10 mm Gaussian kernel).

Statistical analyses

Preprocessed data were analyzed in SPM5 in two full factorial designs (for gray and white matter independently) using age and gender as covariates. We first examined regions with reduced volume in each patient group compared to controls. We then conducted a conjunction analysis of the two previous comparisons (AL < CS and KS < CS) to reveal brain abnormalities shared between the two patient groups. For these analyses, we used a p value of $p < 0.05$ corrected for False Discovery Rate (FDR). We then assessed whether there was any area of significantly greater brain damage in KS compared to AL (within the regions significantly damaged in KS

compared to controls). We thus assessed the contrast KS-AL with the contrast KS-CS as a mask and using a less stringent p value $p < 0.001$ uncorrected for multiple comparisons. Indeed, the differences between these two pathologies are more subtle than the differences between each of these pathologies and the controls, so that a more permissive threshold should be employed to avoid false negative. When necessary, average signal within significant clusters were extracted and post-hoc tests (Tukey's test) were conducted. For all analyses, we used an extended threshold of 200 voxels.

A confirmatory analysis was also conducted in age-matched subgroups of participants with equal sample sizes (supplementary data e-1).

Results

Analyses of gray matter volume

As illustrated in Figure 1A and B, the analysis revealed widespread gray matter damage in both AL and KS patients compared to controls. The conjunction analysis indicated extended areas of shared gray matter volume deficits between AL and KS patients, notably bilaterally in the orbitofrontal cortex extending to the parietal lobe, and in the cingulate cortex, insula, medial temporal lobes, thalami, hypothalamus, and cerebellum ($p < 0.05$ FDR corrected, Figure 1C). Graded effects of volume deficits (KS < AL < CS; $p < 0.01$ in all cases) were found in the medial portion of the thalami, hypothalamus (mammillary bodies) and left insula (Figure 2A). Using a 6 mm Gaussian kernel yielded similar results.

Figure 1 about here

Analyses of white matter volume

Figure 1D and E illustrates white matter volume deficits in AL and KS patients compared to controls. The conjunction analysis revealed shared white matter volume deficits in AL and KS patients in the corpus callosum and cerebellar peduncles and bilaterally in the fornix and cingulum (Figure 1F). There were graded effects of brain damage in the corpus callosum (KS < AL < CS; $p < 0.01$ in all cases) but the left thalamic radiation was exclusively affected in the KS (Figure 2B).

Figure 2 about here.

Discussion

The present voxel-based comparison of gray and white matter indicated striking similarities in the regional distribution and severity of brain damage in AL and KS. This finding confirms the widespread direct or indirect (dietary deficiencies) neurotoxic effects of chronic alcohol consumption on the structure of the brain. The frontocerebellar circuit was affected to the same extent in AL and KS, in agreement with neuropsychological data collected in other groups of AL and KS, which indicated similar pattern of working memory deficits and executive dysfunction in each of the two groups (10). Even though we found volume deficits in Papez's circuit in both patient groups, this circuit was more severely damaged in KS than in AL in agreement with a previous neuroimaging investigation (8). Moreover, the left thalamic radiation was the only brain region to be exclusively altered in KS (with the statistical threshold used here). These findings fit with the fact that episodic memory is impaired both in AL and KS but that the main neuropsychological feature that distinguishes AL and KS is the severity of amnesia (10).

Only a few cerebral regions, including the medial thalami, mammillary bodies and corpus callosum, were more severely damaged in KS than in AL, suggesting that the continuum of macrostructural damage from AL to KS is selective to key brain structures. Statistical cluster analyses (Supplementary data e2) indicated that alcoholics with medial thalamic volume inferior to 2 standard deviations from controls were included within the same cluster as KS patients. Longitudinal investigations are required to determine whether those AL are at risk to develop Korsakoff's syndrome.
