An interesting approach has been proposed by Saint-Anne Hospital (Paris) to differentiate malignant glioneuronal tumors (MGNTs) from WHO grade III and IV malignant gliomas: in a previous study concerning 49 patients classified as WHO grade IV, 10 have been identified as MGNT with a survival twice longer as glioblastomas and a lower occurrence of metastases. Gross total surgical resection may be curative in some cases [1–3]. Though MGNT histologically resemble any WHO grade III or IV glioma, they have a different biological behavior. Neurofilament protein (NFP) immunostaining is strictly required for identification of MGNT by pathologist [3] and has been considered as the gold standard for this study even if it is not the only one discriminant parameter taken into account by pathologists.

Compared to histology or molecular biology, magnetic resonance imaging: (i) associates a large range of complementary acquisition and postprocessing modalities as, for instance, diffusion weighted imaging (DWI) or susceptibility-weighted imaging (SWI), dynamic contrast-enhanced (DCE) MRI or texture analysis (MRI-TA) [4–8], (ii) is performed in vivo and then could contribute to

1. Introduction

Glioblastomas represent the majority of the glial tumors, but their phenotypic and genotypic heterogeneities are large, as attested by the appellation “glioblastoma multiforme”. Their World Health Organization (WHO) classification is mainly based on histological criteria. As the result of a consensus, the classification associates several concepts that are discussed and debated. New approaches of malignant gliomas grading are requested for treatment individualization as well as for the development of new drugs and treatment strategies.

An interesting approach has been proposed by Saint-Anne Hospital (Paris) to differentiate malignant glioneuronal tumors (MGNTs) from WHO grade III and IV malignant gliomas: in a previous study concerning 49 patients classified as WHO grade IV, 10 have been identified as MGNT with a survival twice longer as glioblastomas and a lower occurrence of metastases. Gross total surgical resection may be curative in some cases [1–3]. Though MGNT histologically resemble any WHO grade III or IV glioma, they have a different biological behavior. Neurofilament protein (NFP) immunostaining is strictly required for identification of MGNT by pathologist [3] and has been considered as the gold standard for this study even if it is not the only one discriminant parameter taken into account by pathologists.

Compared to histology or molecular biology, magnetic resonance imaging: (i) associates a large range of complementary acquisition and postprocessing modalities as, for instance, diffusion weighted imaging (DWI) or susceptibility-weighted imaging (SWI), dynamic contrast-enhanced (DCE) MRI or texture analysis (MRI-TA) [4–8], (ii) is performed in vivo and then could contribute to
early diagnosis and treatment followup, and (iii) allows the mapping of intra or peritumoral heterogeneity which is a highly difficult challenge when analysing biopsies or surgical pieces. Even if genomics and proteomics will probably be in a near future the gold standard for tumor subtyping, our challenge, on the basis of the example of MGNT, was to illustrate a potential important contribution from presurgical functional MRI data. Using two complementary methods on the same set of MR images, a static one (MRI-TA) and a dynamic one (DCE-MRI), the challenge was to in vivo characterize the subclass of MGNT and to demonstrate that MRI could usefully contribute to revisit the malignant glioma typing even if an early typing of these tumors do not modify the surgery strategy.

2. Patients and Methods

2.1. Patients. Nineteen patients (9 female and 10 male patients; median age, 57 years; range 40–71 years) with grade IV gliomas according to the WHO classification were selected a posteriori for this study: 8 Glioblastoma (GBM) and 11 MGNT according to the Saint-Anne classification.

2.2. Pathology. All patients underwent a subtotal or a gross total resection, and a single experienced neuropathologist reviewed histological specimens. The evaluated histological parameters included necrosis, vascular proliferation, mitosis, presence of giant cells and cell, density. Tumor necrosis was recorded as present when observed in at least one area in the total histological samples available. Percentage of necrosis was estimated by analysis of the totality of the area in the total histological samples available. Percentage was recorded as present when observed in at least one presence of giant cells and cell, density. Tumor necrosis parameters included necrosis, vascular proliferation, mitosis, total resection, and a single experienced neuropathologist.

All patients underwent a subtotal or a gross total resection. Nineteen patients (9 female and 10 male patients; median age, 57 years; range 40–71 years) with grade IV gliomas according to the WHO classification were selected a posteriori for this study: 8 Glioblastoma (GBM) and 11 MGNT according to the Saint-Anne classification.

2.3. Dynamic MRI Acquisition and Longitudinal Relaxation Rate Measurements. 2D MRI serial acquisitions were performed with a head coil on a 1.5 T imager (GE Signa, Milwaukee, USA). The quantitative MR Imaging protocol has been adapted from previously published studies [9, 10]. 2D fast multiplanar spoiled gradient echo (FMPSPGR) sequences (TR/TE = 150/5.6 ms and variable flip angle, $\theta_1 = 10^\circ$, $\theta_2 = 90^\circ$) were performed. Thirteen sagittal slices were acquired with a field of view of 180 mm × 240 mm, a slice thickness of 5 mm, and a 192 × 256 matrix leading to spatial resolution of 0.94 mm × 0.94 mm. Five longitudinal relaxation time (T1) calibration vials (T1 ranging from 120 ms to 2174 ms at 1.5 T and 19°C) were positioned in the coil and simultaneously imaged with the patient. For parameter extraction, regions of interest (ROI) including about 1500 pixels were manually positioned on the tumor and on the calibration vials on postcontrast images and on the corresponding part of the precontrast image. Before contrast injection, the initial longitudinal relaxation rate $R_{10}$ value of each ROI was obtained with the two images acquired with the 2 different flip angles ($\theta_1 = 10^\circ$, $\theta_2 = 90^\circ$). After a bolus injection of a 0.1 mmol·Kg$^{-1}$ dose of Gd-DOTA (DOTAREM, Guerbet, France), the dynamic relaxometry curves were recorded during 15 minutes. In order to increase temporal resolution, only one T1 weighted acquisition with a $\theta_2 = 90^\circ$ flip angle was performed for each measurement. Indeed, for small flip angles the signal is independent on $R_1$ and does not change after gadolinium injection. For each set of images, the temporal resolution was 28 seconds.

2.4. Physiological Parameters Extraction from DCE-MRI. Postprocessing of DCE-MRI was done with tools developed for ImageJ (ImageJ, Rasband, W.S., US National Institutes of Health, Bethesda, MD, USA http://rsb.info.nih.gov/ij/, 1997–2011) and IDL 5.2 (Research System Incorporation, Boulder, CO, USA). After injection of a bolus $D$ (mmol·kg$^{-1}$) of Gd-DOTA, which distributes in the extracellular space, the relaxation rate of the tissue at time $t$ after the injection is

$$R_1(t) = R_{10} + r v_2 \cdot C_{EES}(t),$$

where $r$ (mmol·s$^{-1}$) is the relaxivity of the extracellular fluid, $C_{EES}$ the contrast agent concentration in the extravascular extracellular space (EES) at time $t$, $R_{10}$ (s$^{-1}$) the relaxation rate before contrast injection, and $R_1(t)$ (s$^{-1}$) the relaxation rate after contrast injection.

At time $t$ after contrast injection, the plasma concentration is given by the exponential relation(6)

$$C_p(t) = D \cdot \sum_{i=1,2} a_i \cdot e^{-m_it},$$

$a_i$ and $m_i$ are plasmatic constants describing the early mixing phase ($i = 1$) and the later extraction phase ($i = 2$). On the Basis of Weinmann et al. data [11], Tofts and Kermode established that for Gd-DTPA $a_1 = 3.99$ kg·l$^{-1}$, $a_2 = 4.78$ kg·l$^{-1}$, $m_1 = 0.144$ min$^{-1}$, and $m_2 = 0.011$ min$^{-1}$.
using the model described by Tofts and Kermode [12], the contrast agent concentration in EES is

\[
C_{\text{EES}}(t) = \frac{K^{\text{trans}}}{v_e} \cdot \frac{\sum_{i=1,2} a_i \cdot \left( e^{-\left( K^{\text{trans}}/v_e \right) t} - e^{-m_i t} \right)}{m_i - \left( K^{\text{trans}}/v_e \right)},
\]

(3)

\(K^{\text{trans}} \text{ (min}^{-1}\)) is the transfer constant which characterizes the blood-tissue exchange processes. From (1) and (3), we obtain

\[
\Delta R_1(t) = R_1(t) - R_{10}
\]

\[
= K^{\text{trans}} \cdot r \cdot \sum_{i=1,2} a_i \cdot \left( e^{-\left( K^{\text{trans}}/v_e \right) t} - e^{-m_i t} \right) \frac{m_i - \left( K^{\text{trans}}/v_e \right)}{m_i - \left( K^{\text{trans}}/v_e \right)},
\]

(4)

\(K^{\text{trans}}\) and \(v_e\) are calculated by fitting the experimental data on (4) using the Levenberg-Marquadt nonlinear regression method. In addition to transfer constant \(K^{\text{trans}} \text{ min}^{-1}\) and EES fraction \(v_e\), the following parameters were computed from the fitted \(\Delta R_1(t)\) curves: maximum relaxation rate \((\Delta R_1 \text{ max s}^{-1})\), time to peak \((\text{TTP s})\), and slopes at \(30\) s \((s30 \text{ s}^{-2})\).

2.5. MRI Texture Analysis. On each tumor, one Region Of Interest (ROI) of around 1500 pixels was selected by the radiologist. Mazda imaging analysis software (Institute of Electronics, Technical University of Lodz, Poland, version 3.20 http://www.eletel.p.lodz.pl/programy/mazda/) was used for texture parameters calculation in ROIs. Three statistical methods of TA were applied giving different texture parameters: (i) gray level histogram (GLH) parameters (mean, variance, skewness, kurtosis, and percentiles) that provide statistics on signal intensity distribution, (ii) co-occurrence matrix (COM) parameters (e.g., entropy, energy, correlation, contrast, inverse difference moment, etc.); this matrix provides statistics on the joint gray-level relationships by evaluating the probability that a gray level \(i\) occurs, at a distance \(d\) and angle \(\theta\), from another gray level \(j\) in the image, thus evaluating image homogeneity, directionality and internal arrangement, and (iii) the run-length distribution matrix (RLM) parameters (gray level distribution, run-length distribution, run percentage, etc.); these parameters describe mainly the coarseness of the image. A “run” is defined as a sequence of identical gray level values in a certain

Table 2: MRI and pathology data (magnetic resonance imaging).
direction. This method calculates the probability function $p(i, d)$ in which each gray level $i$ has a run of length $d$. Further details of these methods can be found in [13].

2.6. Statistical Analysis. The Mann-Whitney test was used for the estimation of statistical significance of imaging parameters. A $P$ value less than 0.05 was considered as statistically significant. Principal component analysis (PCA) and hierarchical ascendant classification (HAC) were performed for each class of TA parameters and for parameters from DCE-MRI. Analysis were performed with Xlstat (Addinsoft, Paris, France). Positive predictive value (PPV), negative predictive value (NPV), sensitivity, and specificity have been calculated from HAC.

3. Results

3.1. Pathology. All tumors exhibited GFAP expressing cells with great variation in tumor areas. Neurofilament positive tumor cells were present in 11 cases. These tumoral cells were cytologically indistinct from other tumor cells with great variation in their number between the different cases. All tumors exhibited marked nuclear atypia and high rate of vascular proliferation. Mitosis were present in all cases with a mean of 25 mitosis/10 HPF for GBM group and 21 mitosis/10 HPF for MGNT group. Tumoral necrosis was noted in all cases with a mean of 50% for GBM group and 38% for MGNT group. Only one GBM displayed moderate cellular density (12%), other cases presenting a high cellular density. In MGNT group, 5 cases were moderately cellular (45%). Numerous multinucleated giant cells were observed in 2 GBM (25%) and in 5 MGNT (45%). Accentuation of the reticulin network was always noted and lymphocytic perivascular cuffing was seen in 2 GBM (25%) and 7 MGNT (63%) (Tables 1 and 2).

3.2. MRI Visual Examination. Visual examination of MR images by the neuroradiologist before and after contrast agent does not discriminate MGNT. The two expected MRI morphological signs for MGNT characterization, meningotropism in MGNT and ring structure in other WHO glioblastomas, are not significant (Tables 1 and 2). However, Figure 1 shows typical well delimited ring pattern of GBM and a more complex “grape-like” appearance of the presented MGNT.

3.3. DCE-MRI. Parameters describing enhancement curve and physiological parameters have been calculated for each patient (Tables 1 and 2). These parameters can be presented as physiological maps (Figure 1).

3.4. Texture Analysis. Parameters from the GLH, COM, and RLM were extracted from postinjection T1 weighted images (Tables 1 and 2).

3.5. Statistical Analysis. Using independently the two methods, MRI-TA and DCE-MRI, a rather poor discrimination between GBM and MGNT is obtained. Although higher values of $K_{\text{trans}}$ and $s30$ are observed for MGNT, there are no statistical significant differences for DCE-MRI related parameters. From the best selected TA features horizontal run length nonuniformity (hRLN) and horizontal grey level nonuniformity (hGLN) from the run length matrix method present a statistical significant difference between MGNT and GBM with $P$ values, respectively, $P = 0.008$ and $P = 0.017$. When associating both MRI-TA and DCE-MRI, 45% of the information is given by the 3 first factorial axis which are mainly weighted by hRLN, hGLN and by angular second moment (ASM), sum entropy and entropy from the cooccurrence matrix method. 11/11 correct classification of MGNT is obtained (Table 3) with a positive predictive value of 79%, a negative predictive value of 100%, a sensitivity of 100%, and a specificity of 62%.

4. Discussion

Though DCE-MRI has already been used in neuro-oncology, previous results have mainly concerned low versus high WHO grades [14–16] and have not revisited the WHO grading of malignant gliomas. Also, MRI texture analysis has opened exciting perspectives in the evaluation of intra-, peri-, and extratumoral heterogeneity but has not been already oriented to an attempt of malignant gliomas subgrading [4, 5].

This study associating DCE and TA is, at our knowledge, the first attempt to in vivo indentify the subclass of MGNT from glioblastoma. Associating DCE-MRI and MRI-TA, a sensitivity of 100% and a specificity of 62% have been obtained in the limited population already studied. The rather low specificity may be improved by adding texture parameters from T2 and/or diffusion weighted images as well as by 3D TA approaches. This preliminary result suggests that in vivo MRI associated with appropriate postprocessing methods could characterize MGNT up to now identified by ex vivo immunostaining histology. One important parameter in pathology typing of MGNT is the angiogenic status, well expressed by the $K_{\text{trans}}$ parameter in DCE MRI. It has
Figure 1: From top to bottom T1-weighted MR image before and 3 min after contrast agent injection, calculated map of transfer constant ($K_{trans}$ in min$^{-1}$) and of extracellular extravascular space fraction ($v_e$ in %). An example of a malignant glioneuronal tumor is on the left and of a glioblastoma is on the right. The color code increases from purple to red. On the postcontrast T1 images the MGNT shows a complex structure, whereas the GBM sows a typical enhanced ring.

also to be noticed that the relevant MRI-TA parameters are second order parameters, then not detected by the visual observation of the radiologist who only can detect first order texture. Concerning other WHO high-grade gliomas, it has to be noticed a large heterogeneity concerning these DCE-MRI and MRI-TA parameters, suggesting again the clinical interest of tumor individualization.

5. Conclusion

These preliminary results show the potential interest of DCE-MRI and MRI-TA association for in vivo tumor characterization, an exciting challenge for subtyping of glioblastoma. Furthermore, if associated with molecular tumor characterization by genomics or proteomics, functional imaging has the potential to provide additional information on tumor heterogeneity, a highly relevant parameter for tumor grading.
