## ABSTRACT

A version of the nonparametric bootstrap, which resamples the entire subjects from original data, called the case bootstrap, has been increasingly used for estimating uncertainty of parameters in mixed-effects models. It is usually applied in order to get more robust estimates of the parameters and more realistic confidence intervals. Alternative bootstrap methods, such as residual bootstrap and parametric bootstrap which resample both random effects and residuals, have been proposed to better take into account the hierarchical structure of multi-level and longitudinal data. However, few studies [have been](#) done to compare these different approaches. In this study, we used simulation to evaluate bootstrap methods proposed for linear mixed-effect models. [We also compared the results obtained by maximum likelihood \(ML\) and restricted maximum likelihood \(REML\).](#) Our simulation studies evidenced the good performance of the case bootstrap as well as the bootstraps of both random effects and residuals. On the other hand, the bootstrap methods which resample only the residuals and the bootstraps combining case and residuals performed poorly. [REML and ML provided similar bootstrap estimates of uncertainty, but there was slightly more bias and poorer coverage rate for variance parameters with ML in the sparse design.](#) We applied the proposed methods to a real dataset from a study investigating the natural evolution of Parkinson's disease and were able to confirm the methods provide plausible estimates of uncertainty. [Given that most real-life datasets tend to exhibit heterogeneity in sampling schedules, the residual bootstraps would be expected to perform better than the case bootstrap.](#)

**KEYWORDS:** bootstrap; longitudinal data; Parkinson's disease; linear mixed-effects models; R.

# 1 INTRODUCTION

Mixed-effects models are commonly used to analyze longitudinal data which consist of repeated measures from individuals through time [1]. They play an important role in medical research, particularly in clinical trials. These models incorporate the fixed effects, which are parameters representing effects in the entire population, and random effects, which are associated with individuals sampled from a population [2]. The parameters of a model are estimated by maximum likelihood (ML) or restricted maximum likelihood (REML) method. In linear mixed-effects models, REML is often preferred to ML estimation because it takes into account the loss of the degrees of freedom involved in estimating the fixed effects, resulting in unbiased estimates of variance components in many situations [2, 3].

The standard errors (SE) of parameter estimates are obtained asymptotically from the inverse of the Fisher information matrix [2, 3]. The above estimates of SE might be biased when the asymptotic approximation is incorrect, for example when the sample-size is small. Sometimes, they can not be obtained when the model is complex or the design is too sparse. Bootstrap methods represent an alternative approach for estimating the SE of parameters, as well as to provide a confidence interval without assuming it is symmetrical. It was first introduced by Efron (1979) for independent and identically distributed (iid) observations. The principal idea of bootstrap is to resample the observed data repeatedly to create datasets similar to the original dataset, then fit them to construct the distribution of an estimator or a statistic of interest [4, 5]. Four main bootstrap approaches have been proposed for simple linear regression: case bootstrap, residual bootstrap, parametric bootstrap and wild bootstrap [6, 7, 8, 9]. The case bootstrap is the most simple and intuitive form which consists in resampling the entire vector of observations with replacement. The residual bootstrap resamples the residuals after model fitting. The parametric bootstrap adopts the principle of residual bootstrap but, instead of directly resampling observed residuals, we simulate the residuals from the estimated distribution, e.g. the normal distribution, whose parameters are estimated using the original data. The wild bootstrap consists in resampling the residuals from an external distribution satisfying certain specifications.

The main concern when bootstrapping is how to generate a bootstrap distribution close to the true distribution of the original sample. To do that, the bootstrap resampling should appropriately mimic the "true" data generating process (DGP) that produced the "true" dataset [10, 11, 12]. In the context of repeated measurement data and mixed-effects modeling, the bootstrap should therefore respect the true DGP with the repeated measures within a subject and handle two levels of variability: between-subject variability and residual variability. The classical bootstrap methods developed in simple linear regression should be modified to take into account the characteristics of mixed-effects models [13]. Resampling random effects may be coupled with resampling residuals [10, 13, 14, 15]. The case bootstrap can be combined with the residual bootstrap [8]. The performance of these approaches are, however, not well studied.

In this paper, we extend different bootstrap approaches which can be applied to linear mixed-effects models settings. The detail of bootstrap methods are described in Section 2. The simulation settings are described in Section 3. The results of the simulation studies and the application of the bootstraps to real data collected in a study in Parkinson's disease are described in Section 4. The discussion of the study is given in Section 5.

## 2 METHODS

### 2.1 Statistical models

Let  $\mathbf{Y}$  be the response variable.  $N$  denotes the number of subjects. Let  $y_{ij}$  denote the observation  $j$  of  $\mathbf{Y}$  in subject  $i$ , while  $\mathbf{y}_i = (y_{i1}, y_{i2}, \dots, y_{in_i})'$  regroups the  $(n_i \times 1)$  vector of measurements in this subject. Let  $n_{tot} = \sum_{i=1}^N n_i$  denote the total number of observations. We use the following linear mixed-effects model (LMEM) [16]:

$$\begin{cases} \mathbf{y}_i = \mathbf{X}_i\boldsymbol{\beta} + \mathbf{Z}_i\boldsymbol{\eta}_i + \boldsymbol{\epsilon}_i \\ \boldsymbol{\eta}_i \sim N(0, \Omega) \\ \boldsymbol{\epsilon}_i \sim N(0, \sigma^2\mathbf{I}_{n_i}) \end{cases} \quad (1)$$

where  $\mathbf{X}_i$  and  $\mathbf{Z}_i$  are  $(n_i \times p)$  and  $(n_i \times q)$  design matrices,  $\boldsymbol{\beta}$  is the  $(p \times 1)$  vector containing the fixed effects,  $\boldsymbol{\eta}_i$  is the  $(q \times 1)$  vector containing the random effects, and  $\boldsymbol{\epsilon}_i$  is the  $(n_i \times 1)$  vector of residual components.  $\Omega$  is the general  $(q \times q)$  covariance matrix with  $(i, j)$  element  $\omega_{ij} = \omega_{ji}$  and  $\sigma^2\mathbf{I}_{n_i}$  is the  $(n_i \times n_i)$  covariance matrix for residual errors in subject  $i$  where  $\sigma^2$  is the error variance and  $\mathbf{I}_{n_i}$  is the  $(n_i \times n_i)$  identity matrix. The random effects  $\boldsymbol{\eta}_i$  are assumed to be normally distributed with mean 0 and covariance matrix  $\Omega$  and the residual errors  $\boldsymbol{\epsilon}_i$  are assumed to be normally distributed with mean zero and variance  $\sigma^2\mathbf{I}_{n_i}$ . The random effects  $\boldsymbol{\eta}_i$  and the residual errors  $\boldsymbol{\epsilon}_i$  are assumed to be independent for different subjects and to be independent of each other for the same subject.

Conditional on the random effects  $\boldsymbol{\eta}_i$ , the response  $\mathbf{Y}_i$  in subject  $i$  is normally distributed with mean vector  $\mathbf{X}_i\boldsymbol{\beta} + \mathbf{Z}_i\boldsymbol{\eta}_i$  and with covariance matrix  $\sigma^2\mathbf{I}_{n_i}$ .

### 2.2 Estimation methods

The parameters of linear mixed-effects models can be estimated in the framework of maximum likelihood by two general methods: maximum likelihood (ML) or restricted maximum likelihood (REML). Let  $\alpha$  denote the vector of all variance components of  $\mathbf{V}_i = \mathbf{Z}_i\Omega(\mathbf{Z}_i)' + \Sigma_i$ , it means  $\alpha$  consists of the  $q(q+1)/2$  different elements in  $\Omega$  (or  $q$  elements if  $\Omega$  is diagonal) and of all parameters in  $\Sigma_i$ . Let  $\theta = (\boldsymbol{\beta}', \boldsymbol{\alpha}')$  be the  $(s \times 1)$  vector of all parameters in the marginal model for  $\mathbf{Y}_i$ . The parameter estimates are obtained by maximizing the marginal likelihood function with respect to  $\theta$ . The ML likelihood function is defined as:

$$L_{ML}(\theta) = \prod_{i=1}^N \left\{ (2\pi)^{-n_i/2} |\mathbf{V}_i|^{-\frac{1}{2}} \times \exp \left( -\frac{1}{2} (\mathbf{y}_i - \mathbf{X}_i \boldsymbol{\beta})' \mathbf{V}_i^{-1} (\mathbf{y}_i - \mathbf{X}_i \boldsymbol{\beta}) \right) \right\} \quad (2)$$

The REML likelihood function is derived from  $L_{ML}(\theta)$  to correct the loss of the degrees of freedom involved in estimating the fixed effects:

$$L_{REML}(\theta) = \left| \sum_{i=1}^N \mathbf{X}_i' \mathbf{V}_i^{-1} \mathbf{X}_i \right|^{-\frac{1}{2}} L_{ML}(\theta) \quad (3)$$

In this study, we used REML as the estimation method. However, we also compared the results of REML with those of ML and presented them in Appendix (available online as Supplementary Material).

When  $\alpha$  is known, the maximum likelihood estimator (MLE) of  $\beta$ , obtained from maximizing  $L_{ML}(\theta)$ , conditional on  $\alpha$ , is given by:

$$\hat{\beta}(\alpha) = \left( \sum_{i=1}^N \mathbf{X}_i' \mathbf{V}_i^{-1} \mathbf{X}_i \right)^{-1} \sum_{i=1}^N \mathbf{X}_i' \mathbf{V}_i^{-1} \mathbf{y}_i \quad (4)$$

When  $\alpha$  is unknown, but an estimate  $\hat{\alpha}$  is available, we can set  $\mathbf{V}_i = \hat{\mathbf{V}}_i$  and estimate  $\beta$  by using equation 4.

Estimates of the  $\boldsymbol{\eta}_i$  can be obtained as the mean of the posterior distribution of  $\boldsymbol{\eta}_i$  (empirical Bayes estimates, EBEs):

$$\hat{\boldsymbol{\eta}}_i(\theta) = E[\boldsymbol{\eta}_i | \mathbf{y}_i] = \int \boldsymbol{\eta}_i f(\boldsymbol{\eta}_i | \mathbf{y}_i) d\boldsymbol{\eta}_i = \Omega \mathbf{Z}_i' \mathbf{V}_i^{-1} (\mathbf{y}_i - \mathbf{X}_i \boldsymbol{\beta}) \quad (5)$$

The MLE  $\hat{\theta}$  of  $\theta$  is asymptotically normally distributed with mean  $\theta$  and asymptotic covariance matrix given by the inverse of the Fisher information matrix  $M_F$ . The asymptotic SE of parameters are then estimated as the square root of the diagonal element of the estimated covariance matrix.

### 2.3 Bootstrap methods

The principle of the bootstrap is to repeatedly generate pseudo-samples distributed according to the same distribution as the original sample. The unknown original distribution may be replaced by the **empirical** distribution of the sample, which **is known as** the nonparametric bootstrap [17]. The bootstrap exists in another version called the parametric bootstrap [7, 9]. In this version, the underlying distribution  $F$  is estimated from the data by a parametric model, for instance a normal distribution and bootstrap samples are generated by simulating within

this distribution rather than from the empirical distribution as performed in the nonparametric version. The resampling can be done with an independent distribution; this procedure is called external bootstrap or wild bootstrap. This approach was proposed by Wu to deal with heteroscedasticity [18]. We have chosen to deal with the simpler case of homoscedasticity and therefore have not investigated the wild bootstrap.

Let  $B$  be the number of bootstrap samples to be drawn from the original dataset, a general bootstrap algorithm is:

1. Generate a bootstrap sample by resampling from the data and/or from the estimated model
2. Obtain the estimates for all parameters of the model for the bootstrap sample
3. Repeat steps 1-2  $B$  times to obtain the bootstrap distribution of parameter estimates and then compute mean, standard deviation, and 95% confidence interval of this distribution

Let  $\hat{\theta}_b^*$  be the parameter estimated for the  $b^{th}$  bootstrap sample. [Given a data set, the expected value of the bootstrap estimator over the bootstrap distribution](#) is calculated as the average of the parameter estimates from the  $B$  bootstrap samples:

$$\hat{\theta}_B = \frac{1}{B} \sum_{b=1}^B (\hat{\theta}_b^*) \quad (6)$$

The bootstrap standard error is obtained as the sample standard deviation of the  $\hat{\theta}_b^*$ :

$$\widehat{SE}_B = \sqrt{\frac{1}{B-1} \sum_{b=1}^B (\hat{\theta}_b^* - \hat{\theta}_B)^2} \quad (7)$$

A 95% bootstrap confidence interval can be constructed by calculating the 2.5<sup>th</sup> and 97.5<sup>th</sup> percentile of bootstrap distribution:

$$\hat{\theta}_{(\alpha \cdot B)}^* \leq \theta \leq \hat{\theta}_{((1-\alpha) \cdot B)}^* \quad (8)$$

where  $\alpha=0.025$ . An alternative approach is to use a normal approximation to construct a bootstrap confidence interval, using the estimated  $\widehat{SE}_B$ :

$$\hat{\theta}_B - \widehat{SE}_B \cdot z_{1-\alpha/2} \leq \theta \leq \hat{\theta}_B + \widehat{SE}_B \cdot z_{1-\alpha/2} \quad (9)$$

$z_{1-\alpha/2}$  denotes the  $1 - \alpha/2$  quantile of the standard normal distribution, equal to 1.96 with  $\alpha = 0.05$ . However, it is preferable to use the bootstrap percentile confidence interval when bootstrapping [7, 19].

The detailed algorithms of bootstrap methods to obtain a bootstrap sample (bootstrap generating process) are presented below in two separated groups: nonparametric and parametric bootstrap methods.

### 2.3.1 Nonparametric bootstrap

*Nonparametric case bootstrap* ( $B_{\text{case,none}}$ ). This method consists of resampling with replacement the entire subjects, that is the joint vector of design variables and corresponding responses  $(\mathbf{X}_i, \mathbf{Z}_i, \mathbf{y}_i)$  from the original data before modeling. It is also called the *paired bootstrap*. This procedure omits the second step of resampling the observations inside each subject. However, it is the most obvious way to do bootstrapping and makes no assumptions on the model.

*Nonparametric case bootstrap coupled with global/individual residual bootstrap* ( $B_{\text{case,GR}}$  or  $B_{\text{case,IR}}$ ). This method resamples first the entire subjects with replacement. The individual residuals are then resampled with replacement globally from the residual distribution of the original simulated dataset or individually from the residual distribution of new subjects obtained after bootstrapping in the first step. The bootstrap sample is obtained as follows:

1. Fit the model to the data then calculate the residuals  $\hat{\epsilon}_i = \mathbf{y}_i - \mathbf{X}_i \hat{\boldsymbol{\beta}} - \mathbf{Z}_i \hat{\boldsymbol{\eta}}_i$
2. Draw  $N$  entire subjects  $\{(\mathbf{X}_i^*, \mathbf{Z}_i^*, \mathbf{y}_i^*)\}$  with replacement from  $\{(\mathbf{X}_i, \mathbf{Z}_i, \mathbf{y}_i)\}$  in the original data and keep their predictions from model fitting  $\mathbf{X}_i^* \hat{\boldsymbol{\beta}} + \mathbf{Z}_i^* \hat{\boldsymbol{\eta}}_i^*$  and their corresponding residuals  $\hat{\epsilon}_i^* = \mathbf{y}_i^* - \mathbf{X}_i^* \hat{\boldsymbol{\beta}} - \mathbf{Z}_i^* \hat{\boldsymbol{\eta}}_i^*$ . The new subject has  $n_i^*$  observations.
3. Draw the residuals with replacement globally from all residuals of the original data or individually from each new subject
  - (a) Global residual resampling: draw a sample  $\{\epsilon^*\} = \{\hat{\epsilon}_{i^*j^*}\}$  of size  $n_{tot}^* = \sum_{i=1}^N n_i^*$  with replacement globally from  $\{\hat{\epsilon}\} = \{\hat{\epsilon}_{ij}\}_{i=1,\dots,N;j=1,\dots,n_i}$  by assigning an equal probability  $\frac{1}{n_{tot}}$  to each value of the  $n_{tot}$  residuals (note that,  $n_{tot}^*$  may be different with  $n_{tot}$ )
  - (b) Individual residual resampling: draw individually  $N$  samples  $\{\epsilon_i^*\} = \{\hat{\epsilon}_{ij^*}\}$  of size  $n_i^*$  with replacement from  $\hat{\epsilon}_i^* = \{\hat{\epsilon}_{ij}\}_{j=1,\dots,n_i^*}$  by assigning an equal probability  $\frac{1}{n_i^*}$  to each residual of new subject  $i$
4. Generate the bootstrap responses  $\mathbf{y}_i^* = \mathbf{X}_i^* \hat{\boldsymbol{\beta}} + \mathbf{Z}_i^* \boldsymbol{\eta}_i^* + \boldsymbol{\epsilon}_i^*$

Here, and in the following, we note the vector of estimated residuals for all subjects as  $\hat{\boldsymbol{\epsilon}} = \{\hat{\epsilon}_{ij}\}_{i=1,\dots,N;j=1,\dots,n_i}$  and the vector of estimated residuals in subject  $i$  as  $\hat{\boldsymbol{\epsilon}}_i = \{\hat{\epsilon}_{ij}\}_{j=1,\dots,n_i}$ .

*Nonparametric random effects bootstrap coupled with global/individual residual bootstrap* ( $B_{\eta,\text{GR}}$  or  $B_{\eta,\text{IR}}$ ). This method consists of resampling with replacement the random effects obtained after model fitting, as well as the residuals globally or individually. The bootstrap sample is obtained as follows:

1. Fit the model to the data then estimate the random effects  $\hat{\boldsymbol{\eta}}_i$  and the residuals  $\hat{\epsilon}_i = \mathbf{y}_i - \mathbf{X}_i \hat{\boldsymbol{\beta}} - \mathbf{Z}_i \hat{\boldsymbol{\eta}}_i$
2. Draw a sample  $\{\boldsymbol{\eta}_i^*\}$  of size  $N$  with replacement from  $\{\hat{\boldsymbol{\eta}}_i\}$  by assigning an equal probability  $\frac{1}{N}$  to each value

3. Draw a sample  $\{\epsilon^*\}=\{\hat{\epsilon}_{i^*j^*}\}$  of size  $n_{tot}$  with replacement globally from  $\{\hat{\epsilon}\}$  or draw individually  $N$  samples  $\{\epsilon_i^*\}=\{\hat{\epsilon}_{ij^*}\}$  of size  $n_i$  with replacement from  $\{\hat{\epsilon}_i\}$
4. Generate the bootstrap responses  $\mathbf{y}_i^* = \mathbf{X}_i\hat{\boldsymbol{\beta}} + \mathbf{Z}_i\boldsymbol{\eta}_i^* + \epsilon_i^*$

*Nonparametric global/individual residual bootstrap* ( $\mathbf{B}_{\text{none,GR}} / \mathbf{B}_{\text{none,IR}}$ ). For the sake of completeness, we also implemented a bootstrap where only residual variability is resampled. These procedures do not resample the between-subject variability (which remains in the model through the estimated random effects  $\hat{\boldsymbol{\eta}}_i$ ). The bootstrap sample is obtained as follows:

1. Fit the model to the data then calculate the residuals  $\hat{\epsilon}_i = \mathbf{y}_i - \mathbf{X}_i\hat{\boldsymbol{\beta}} - \mathbf{Z}_i\hat{\boldsymbol{\eta}}_i$
2. Draw a sample  $\{\epsilon^*\}=\{\hat{\epsilon}_{i^*j^*}\}$  of size  $n_{tot}$  with replacement globally from  $\{\hat{\epsilon}\}$  or draw individually  $N$  samples  $\{\epsilon_i^*\}=\{\hat{\epsilon}_{ij^*}\}$  of size  $n_i$  with replacement from  $\{\hat{\epsilon}_i\}$
3. Generate the bootstrap responses  $\mathbf{y}_i^* = \mathbf{X}_i\hat{\boldsymbol{\beta}} + \mathbf{Z}_i\hat{\boldsymbol{\eta}}_i + \epsilon_i^*$

The nonparametric bootstrap methods that resample the random effects or the residuals depend on the structural model to calculate the raw random effects or residuals. However, they do not require particular assumptions on their distributions.

### 2.3.2 Parametric bootstrap

The parametric bootstrap requires the strongest assumptions as it depends both on the model and the distributions of parameters and errors.

*Case bootstrap coupled with parametric residual bootstrap* ( $\mathbf{B}_{\text{case,PR}}$ ). Similar to  $\mathbf{B}_{\text{case,GR}}$ , this methods resamples firstly the subjects and then resamples the residuals by simulating from the estimated distribution. This method **combines elements of both the** nonparametric bootstrap (case bootstrap in the first step) and the parametric bootstrap (residual bootstrap in the second step). However, to simplify the classification, we keep it in the group of parametric bootstraps. The bootstrap sample is obtained as follows:

1. Fit the model to the data
2. Draw  $N$  entire subjects  $\{(\mathbf{X}_i^*, \mathbf{Z}_i^*, \mathbf{y}_i^*)\}$  with replacement from  $\{(\mathbf{X}_i, \mathbf{Z}_i, \mathbf{y}_i)\}$  in the original data and keep their predictions from model fitting  $\mathbf{X}_i^*\hat{\boldsymbol{\beta}} + \mathbf{Z}_i^*\hat{\boldsymbol{\eta}}_i$
3. Draw  $N$  samples  $\{\epsilon_i^*\}$  of size  $n_i^*$  from a normal distribution with mean zero and covariance matrix  $\hat{\sigma}^2\mathbf{I}_{n_i}$
4. Generate the bootstrap responses  $\mathbf{y}_i^* = \mathbf{X}_i^*\hat{\boldsymbol{\beta}} + \mathbf{Z}_i^*\hat{\boldsymbol{\eta}}_i + \epsilon_i^*$

*Parametric random effects bootstrap coupled with residual bootstrap* ( $\mathbf{B}_{\text{PR,PR}}$ ). This methods resamples both random effects and residuals by simulating from estimated distribution after model fitting. The bootstrap sample is obtained as follows:

1. Fit the model to the data

2. Draw a sample  $\{\boldsymbol{\eta}_i^*\}$  of size  $N$  from a multivariate normal distribution with mean zero and covariance matrix  $\hat{\Omega}$
3. Draw  $N$  samples  $\{\boldsymbol{\epsilon}_i^*\}$  of size  $n_i$  from a normal distribution with mean zero and covariance matrix  $\hat{\sigma}^2 \mathbf{I}_{n_i}$
4. Generate the bootstrap responses  $\mathbf{y}_i^* = \mathbf{X}_i \hat{\boldsymbol{\beta}} + \mathbf{Z}_i \boldsymbol{\eta}_i^* + \boldsymbol{\epsilon}_i^*$

*Parametric residual bootstrap* ( $\mathbf{B}_{\text{none,PR}}$ ). Again for exhaustiveness, we implemented a bootstrap which resamples only the residuals by simulating from the estimated distribution after model fitting. Similar to  $\mathbf{B}_{\text{none,GR}}$  or  $\mathbf{B}_{\text{none,IR}}$ , this procedure omits the first step of resampling the between-subject variability. The bootstrap sample is obtained as follows:

1. Fit the model to the data
2. Draw  $N$  samples  $\{\boldsymbol{\epsilon}_i^*\}$  of size  $n_i$  from a normal distribution with mean zero and covariance matrix  $\hat{\sigma}^2 \mathbf{I}_{n_i}$
3. Generate the bootstrap responses  $\mathbf{y}_i^* = \mathbf{X}_i \hat{\boldsymbol{\beta}} + \mathbf{Z}_i \hat{\boldsymbol{\eta}}_i + \boldsymbol{\epsilon}_i^*$

### 2.3.3 Transformation of random effects and residuals

Previous results in the literature show that the nonparametric bootstrap of the raw residuals obtained by model fitting usually yield downwardly biased variance parameter estimates [7, 8, 20]. In ordinary linear models, this underestimation is due to the difference between estimated and empirical variance of residuals [21]. That's why it is advisable to rescale the residuals so that they have the correct variance. Efron suggested to multiply centered raw residuals with the factor  $\sqrt{(n-p)/n}$  where  $p$  is the number of parameters and  $n$  is the number of observations [22]. For the same reason, Davison et al proposed to use the factor  $\sqrt{1/(1-h_i)}$  where  $h_i$  is the  $i^{\text{th}}$  diagonal element of the hat matrix which maps the vectors of observed values to the vector of fitted values [7]. In mixed-effects models, this is because the raw variance-covariance matrix is different from the maximum likelihood estimate, as the raw random effects or residuals are "shrunk" towards 0 [20]. Carpenter et al proposed to take this into account by centering the random effects and residuals to resample from a distribution with mean zero and multiplying them by the ratio between their corresponding estimated and empirical variance-covariance matrices to account for the variance underestimation [20, 23]. These corrections were used in our study.

*Transforming random effects.* The transformation of random effects was carried out in the following steps:

1. Center the raw estimated random effects:  $\tilde{\boldsymbol{\eta}}_i = \hat{\boldsymbol{\eta}}_i - \bar{\boldsymbol{\eta}}_i$
2. Calculate the ratio between the estimated and empirical variance-covariance matrix ( $A_\eta$ ). Let  $\hat{\Omega}$  be the model estimated variance-covariance matrix of random effects and  $\Omega_{emp}$  denote the empirical variance-covariance matrix of the centered random effects  $\tilde{\boldsymbol{\eta}}_i$ . The ratio matrix  $A_\eta$  is formed by using the Cholesky factors  $L_{est}$  and  $L_{emp}$ , which are the lower triangular matrix of the Cholesky decomposition of  $\hat{\Omega}$  and  $\Omega_{emp}$ , respectively:  $A_\eta = (L_{est} \cdot L_{emp}^{-1})'$

3. Transform the centered random effects using the ratio  $A_\eta$ :  $\hat{\eta}'_i = \tilde{\eta}_i \times A_\eta$

*Transforming residuals.* The transformation of residuals was carried out **globally for all residuals** in the following steps:

1. Center the raw estimated residuals:  $\tilde{\epsilon}_{ij} = \hat{\epsilon}_{ij} - \bar{\epsilon}_{ij}$
2. Calculate the ratio between the estimated and empirical variance-covariance matrix ( $A_\sigma$ ). Let  $\hat{\Sigma}$  be the model estimated variance-covariance matrix for residuals, which is assumed to be equal to  $\hat{\sigma}^2 \mathbf{I}_{n_i}$  and  $\Sigma_{emp}$  denote the empirical variance-covariance matrix of centered residual  $\tilde{\epsilon}_{ij}$ . Because the residuals are assumed to be uncorrelated and to have equal variance, the ratio matrix  $A_\sigma$  is then simply the ratio between the square root of the model estimated residual variance  $\hat{\sigma}^2$  and the empirical standard deviation of the centered residuals, respectively:  $A_\sigma = \hat{\sigma} / sd(\tilde{\epsilon}_{ij})$ .
3. Transform the centered residuals using the ratio  $A_\sigma$ :  $\hat{\epsilon}'_{ij} = \tilde{\epsilon}_{ij} \times A_\sigma$

### 3 SIMULATION STUDIES

#### 3.1 Motivating example

The motivating example for bootstrap evaluation was a disease progression model inspired from the model of Parkinson's disease developed by Holford et al [24]. In that study, the subjects were initially randomized to treatment with placebo, with deprenyl, with tocopherol or with both and, when clinical disability required, received one or more dopaminergic agents (levodopa, bromocriptine or pergolide). The aim was to study the influence of various drugs on the changes in UPDRS (Unified Parkinson's Disease Rating Scale) over time. **Several components describing the disease progression and the effect of treatment were developed.** However, in this study, we are only interested in the linear part of the model, describing the natural evolution of Parkinson's disease using a random intercept and slope model as:

$$y_{ij} = S_0 + \alpha \cdot t_{ij} + \eta_{S_0i} + \eta_{\alpha i} \cdot t_{ij} + \epsilon_{ij} \quad (10)$$

where  $y_{ij}$  is the UPDRS score (u) representing the state of disease at time  $t_{ij}$  which was considered to be continuous,  $S_0$  (u) is the expected score at randomization,  $\alpha$  (u/year) is the progression rate,  $\eta_{S_0i}$  (u/year) and  $\eta_{\alpha i}$  (u/year) are the random effects of  $S_0$  and  $\alpha$ , respectively and  $\epsilon_{ij}$  is the residual errors. In the formulation of equation (1), the design matrix  $\mathbf{X}_i = \mathbf{Z}_i$  for subject  $i$  is a two-column matrix with a first column of 1s and a second column containing the  $n_i$  times  $t_{ij}$  for subject  $i$ .

For our simulations, we used the subset of patients who remained in the placebo group over the first 2 years. **The UPDRS scores were measured at randomization and at regular (unscheduled) visits up to 2 years after entry to the study.** This subset contains 109 subjects with an average of 6 observations per subject and a total of 822 observations. **Figure 1** describes the evolution of UPDRS score over a two-year period.

In the paper of Holford et al, the baseline  $S_0$  was assumed to be log-normally distributed, and the progression rate  $\alpha$  was assumed to be normally distributed [24]. The variance of the random effects and the correlation  $\rho$  between  $S_0$  and  $\alpha$  was estimated. The residual unexplained variability was described by an additive model error with constant variance  $\sigma^2$ . In the present study, both  $S_0$  and  $\alpha$  were assumed to be normally distributed. We estimated the parameters of the real dataset by ML, the same estimation method as used in the original publication [24], using the `lme` function in R. The detail of parameter estimates is given in section 4.2.

### 3.2 Simulation settings

Our simulations were inspired from the original design described above using estimates from the real dataset.

Three designs were planned to evaluate the performance of bootstrap. For each design, the sampling times were similar for all subjects.

*Rich design.* We simulated  $N=100$  subjects with  $n=7$  observations per subject at 0, 0.17, 0.33, 0.5, 1, 1.5, 2 years after being entered in the study.

*Sparse design.* We simulated  $N=30$  subjects with  $n=3$  observations per subject at 0, 0.17, 2 years after being entered in the study. This design is sparse with respect to estimation of variance parameters, including only 90 observations in total.

*Large error design.* We simulated  $N=100$  subjects with  $n=7$  observations per subject at 0, 0.17, 0.33, 0.5, 1, 1.5, 2 years after being entered in the study. In this design, we modified the level of variability. The variability for random effects  $\eta_{S_0}$  and  $\eta_\alpha$  were changed to  $\omega_{S_0}=11.09$  and  $\omega_\alpha=6.98$  respectively (equivalent to 50% of the corresponding fixed-effects), and the standard deviation for the residual error was changed to  $\sigma=17.5$ . We also removed the correlation  $\rho$  between  $S_0$  and  $\alpha$  in this design because convergence was obtained for only 78.3% simulated datasets with the presence of this correlation.

For each design, we simulated  $K=1000$  replications.

### 3.3 Software

The `lme` function in the `n1me` library in R was used to fit the data using REML as the estimation method. ML was also used to compare with the results of REML. For both methods, we fitted datasets with the initial values of variance parameters generated by the optimisation procedure implemented in the `lme` function [25]. All the analysis and figures were done with R.

### 3.4 Evaluation of bootstrap methods

Table 1 presents all the bootstrap methods that we implemented and evaluated. The resampling of the between-subject variability (BSV) can be done by resampling subjects or random effects. The resampling of the residual variability (RUV) can be done by resampling of residuals obtained from all subjects, called global residuals or resampling of residuals within each subject, called individual residuals. In order to compare the performance of these bootstraps to that of classical bootstraps, the residual bootstrap, which resamples only the RUV, and the case bootstrap where the whole vector of observations, including both the BSV and RUV, is resampled were also evaluated in our study. The bootstrap methods were classified as nonparametric and parametric methods. For the parametric approach, there is no difference between the global and the individual residual resampling because it is performed by simulation from the estimated distributions. In total, we had 7 nonparametric methods and 3 parametric methods.

We drew  $B=1000$  bootstrap samples for each replication of simulated data and for each bootstrap method. The parameters were estimated by REML method using the `lme` function in R. For each method, we therefore performed 1 million fits (1000 simulated datasets  $\times$  1000 bootstrap datasets). If the convergence was not obtained, the NA was recorded in the table of parameter estimates and excluded for further calculation.

For the  $k^{th}$  simulated dataset and for a given bootstrap method, we computed the bootstrap parameter estimate  $\hat{\theta}_B^k$  as in equation (5), using 1000 bootstrap samples, as well as the bootstrap SE and CI, for each parameter  $\theta$ . The relative bias (RBias) of bootstrap estimate was obtained by comparing the bootstrap estimate  $\hat{\theta}_B^k$  and the asymptotic estimate  $\hat{\theta}_k$  as follows:

$$\text{RBias}(\hat{\theta}_B) = \frac{1}{K} \sum_{k=1}^K \left( \frac{\hat{\theta}_B^k - \hat{\theta}_k}{\hat{\theta}_k} \times 100 \right) \quad (11)$$

The average bootstrap SE was obtained by averaging the SE from equation (6) over the  $K=1000$  datasets. The true SE is unknown, but we can get an empirical estimate as the standard deviation of the differences between the estimate of the parameter in the  $K$  datasets and the true value ( $\theta_0$ ):

$$\text{SE}_{\text{empirical}}(\hat{\theta}) = \sqrt{\frac{1}{K-1} \sum_{k=1}^K (\hat{\theta}_k - \theta_0)^2} \quad (12)$$

The relative bias on bootstrap SE was then obtained by comparing the average bootstrap SE to this empirical SE:

$$\text{RBias}(\text{SE}(\hat{\theta}_B)) = \frac{\frac{1}{K} \sum_{k=1}^K \text{SE}_B(\hat{\theta}_B^k) - \text{SE}_{\text{empirical}}(\hat{\theta})}{\text{SE}_{\text{empirical}}(\hat{\theta})} \times 100 \quad (13)$$

The coverage rate of the 95% bootstrap confidence interval (CI) was defined as the percentage of the  $K=1000$  datasets in which the bootstrap CI contains the true value of the

parameter.

The bootstrap approaches were compared in terms of the Rbias on the bootstrap parameter estimates, the Rbias on SE, and the coverage rate of the 95% CI of all parameter estimates from one million bootstrap samples.

The performance of the bootstrap methods were also compared to the performance of the asymptotic method. It is worth noting that in the simulation studies, random variables were simulated according to normal distributions, which may have contributed to the good performance of the asymptotic method. The relative bias of asymptotic estimate was obtained by comparing the asymptotic estimate  $\hat{\theta}_k$  and the true value  $\theta_0$  as follows:

$$\text{RBias}(\hat{\theta}) = \frac{1}{K} \sum_{k=1}^K \left( \frac{\hat{\theta}_k - \theta_0}{\theta_0} \times 100 \right) \quad (14)$$

The relative bias of asymptotic SEs given by the software (obtained as the inverse of the Fisher information matrix) was defined in the same way as equation (13), but with respect to  $\hat{\theta}_k$  in stead of  $\hat{\theta}_B^k$ . The coverage rate of the 95% asymptotic CI was defined as the percentage of datasets in which the asymptotic CI contains the true value of the parameter.

The asymptotic and bootstrap parameters estimates and their SE were defined as unbiased when relative bias was within  $\pm 5\%$ , moderately biased (relative bias from  $\pm 5\%$  to  $\pm 10\%$ ) or strongly biased (relative bias  $> \pm 10\%$ ). The coverage rate of the 95% CI was considered to be good (from 90% to 100%), low (from 80% to 90%) or poor ( $< 80\%$ ). A good bootstrap was defined as a method providing unbiased estimates for the parameters and their corresponding SE, and ensuring a good coverage rate of the 95% CI.

### 3.5 Application to real data

All the bootstrap methods with good performance evaluated in the simulations studies were applied to the real data by drawing  $B=1000$  bootstrap samples for each method. The bootstrap parameter estimates and bootstrap SE were compared with each other and compared to the parameter estimates and their SEs obtained by the asymptotic approach.

## 4 RESULTS

### 4.1 Simulation studies

Examples of simulated data for each given design are illustrated in Figure 2. Our simulations gave some negative values for the observations because of the homoscedastic error model. These values were kept as is, since the purpose of the simulations was not to provide a realistic simulation of the trial, but only to evaluate the bootstrap methods. For the same reason,

we did not take into account other real-life factors such as drop-outs or missingness.

We present firstly the results of REML. Complete results for all bootstrap methods as well as the asymptotic method in the 3 evaluated designs are reported in Table 2, for relative bias of the bootstrap estimates of parameters and their corresponding SEs, and Table 3, for the coverage rate of the 95% CI. The correlation between  $S_0$  and  $\alpha$  was not estimated in the large error design for both simulated and bootstrap datasets to have better convergence rate and to keep the same model which we simulated. The transformation of random effects and residuals were done before resampling for the methods in which they were resampled nonparametrically. In the rich design, we found that the bootstrap methods which resample only the residuals ( $B_{\text{none,GR}}$ ,  $B_{\text{none,IR}}$ ,  $B_{\text{none,PR}}$ ) yielded higher bias for the correlation term ( $>9.73\%$ ). The same was observed for the case bootstrap coupled with the residual bootstraps ( $B_{\text{case,GR}}$ ,  $B_{\text{case,IR}}$ ,  $B_{\text{case,PR}}$ ). The case bootstrap and the bootstraps of both random effects and residuals ( $B_{\eta,\text{GR}}$ ,  $B_{\eta,\text{IR}}$ ,  $B_{P\eta,\text{PR}}$ ) showed essentially no bias for all parameters. In terms of SE estimation, these four bootstrap methods estimated correctly all the SEs, as the estimates were very close to empirical SEs, while the residual-alone bootstraps greatly underestimated the SEs of all parameters, except for that of  $\sigma$ . On the contrary, the SE of  $\sigma$  was overestimated by the  $B_{\text{case,IR}}$ . The case bootstrap, coupled with global residual bootstrap ( $B_{\text{case,GR}}$ ) or parametric bootstrap ( $B_{\text{case,PR}}$ ), gave better estimates for SE of parameters than the residual-alone bootstraps, but they did not work as well as the case bootstrap and the bootstrap of random effects and residuals. In terms of coverage rate, the residual-alone bootstraps had very poor coverage rates for all parameters ( $< 0.6$ ) except for the SE of  $\sigma$ , while the case bootstrap and the bootstraps of both random effects and residuals provided the good coverage rates (close to the nominal value of 0.95). According to our predefined criteria, four methods showed good performance:  $B_{\text{case,none}}$ ,  $B_{\eta,\text{GR}}$ ,  $B_{\eta,\text{IR}}$  and  $B_{P\eta,\text{PR}}$ . These methods remained the best methods for the sparse design and the large error design, with smaller relative bias for the parameter estimates and their SEs and better coverage rates. The simulation results also showed that the asymptotic approach provided good estimates for parameters and SEs as well as good coverage rates as do the bootstrap candidates. In this simple setting, the convergence rate was high: nearly all runs on the simulated datasets converged (respectively 100%, 99.8% and 99.9% for the rich, sparse and large error designs). Convergence was also close to 100% when applied to the bootstrap samples in the rich (100%) and large error (99.9%) design while for the sparse design, convergence rates were slightly lower and more dependent on the bootstrap method, going from around 90.2% for the bootstraps combining case and residuals, to 96.7% for the case bootstrap or the bootstraps of both random effects and residuals.

In this study, we also evaluated the influence of transformation of random effects and residuals using the ratio between the estimated and empirical variance-covariance matrices. Non-transformed and transformed resampling were compared for all non-parametric bootstrap methods except for the  $B_{\text{case,none}}$  where no transformation was needed. The results of this transformation in the rich design are presented in Figure 3. We found that these corrections improved significantly the estimate of  $\sigma$ , its SE as well as the coverage rate for all applied methods. However, they only improved the estimates and the coverage rates of other

variance parameters for  $B_{\eta,GR}$  and  $B_{\eta,IR}$ .

The results for the bootstrap candidates in the different evaluated designs, providing a more contrasted evaluation of their performance were shown in Figure S1 in Appendix. All the bootstrap candidates provided good parameter estimates in all evaluated designs with the relative bias within  $\pm 5\%$ , except for a higher bias on  $\sigma$  (-6.50%) observed for the  $B_{\eta,IR}$  in the sparse design. The relative bias for the variance estimates were higher for the sparse and the large error designs compared to those of the rich design, while the relative bias of the fixed effects remained very small ( $< 0.1\%$ ). All the bootstrap candidates estimated correctly the SE of parameters, with relative biases ranging from -5% to 5%, observed in both rich and large error designs. They estimated less correctly the SE of variance parameters in the sparse design with relative biases ranging from -10% to 10%, especially for the case bootstrap. The boxplots of the SEs of all parameter estimates obtained by the bootstrap candidates in all evaluated designs are shown in Figure S2 in Appendix. The range of bootstrap standard errors across the  $K=1000$  replications did not show any practically relevant differences across the bootstrap methods, with the exception of SE of  $\sigma$  in the sparse design. A good coverage rate was obtained for all parameters in the rich design setting, as well as the design with large error; the one exception is a low coverage rate for  $\sigma$  observed for  $B_{\eta,IR}$  in the design with large error. In the sparse design, the bootstrap candidates provided lower coverage rate for variance parameters. Across the different designs, the  $B_{P\eta,PR}$  worked slightly better than the  $B_{case,none}$  and the  $B_{\eta,GR}$  performed better than the  $B_{\eta,IR}$ .

In order to understand whether the estimation method influences the performance of the bootstrap methods, we compared the results of ML with those of REML. All the results of ML are given in Appendix with Table S1 and Table S2. The difference between ML and REML in relative bias of parameter estimates and their SEs and coverage rate for all bootstrap methods and the asymptotic method in three evaluated designs are shown in Figure S3 in Appendix. There was no difference in estimation of fixed effects and  $\sigma$  between two methods. However, the variance parameters ( $\omega_{S_0}$  and  $\omega_{\alpha}$ ) given by ML were slightly less well estimated compared to those of REML with increase of 0.5 to 2% in relative bias and had lower coverage rate in all evaluated designs. The difference between ML and REML in estimation of variance parameters was more apparent in the sparse design, resulting in bigger difference in their coverage rates (2 to 5%) observed for all bootstrap methods. In terms of SE estimation, ML and REML provided similar estimates, except for a small difference in relative bias ( $< 2\%$ ) in the sparse design. Based on our criteria about relative bias, REML was better than ML by providing unbiased estimates for almost parameters obtained by four bootstrap candidates. REML also improved the coverage rate of variance parameters in the sparse design while it provided similar estimates of SEs compared to ML.

## 4.2 Application to real data

The asymptotic parameter estimates by ML and their SEs for the real dataset were given in the first row of Table 4; these were taken as the true parameter values used in the simulation study reported above. The parameter estimates by REML and the SEs of all parameters obtained by the asymptotic method and the 4 bootstrap candidates for the real dataset are also shown in Table 4. They provided similar values for both fixed-effect and variance parameters which were also close to the asymptotic estimates. However, there were some differences for the estimation of SE of  $\alpha$ ,  $\omega_\alpha$  and  $\sigma$  between the bootstrap methods. The  $B_{\text{case,none}}$  yield the highest SE for these parameters while the  $B_{P\eta,PR}$  and the asymptotic estimates were very similar, which were both different from the remaining bootstrap methods. This finding was not observed in the simulation study, where balanced designs with the same number of observations per subject were used and the residuals were normally distributed. The distribution of the empirical residuals in the real dataset was investigated and a non normal distribution was confirmed by the Shapiro-Wilk normality test. The similar results of ML for the real data are also presented in Table S3 in Appendix.

In order to investigate the effect of the unbalance in the design, we stratified the case bootstrap based on the number of observations per subject (nobs). The real dataset was divided into 3 groups before bootstrapping: group 1 (N=40 subjects with nobs  $\leq 5$ ), group 2 (N=38 subjects with nobs  $> 5$  and  $\leq 10$ ) and group 3 (N=31 subjects with nobs  $> 10$ ). The bootstrap samples were then built by sampling subjects within each group, keeping the same number of subjects from each group. The results obtained from this analysis are also given in Table 4. The case bootstrap with stratification  $B_{\text{case,none}}^{\text{strat}}$  gave similar values for parameters as the case bootstrap and other bootstrap methods. In terms of SE of parameters, this method provided smaller values for SEs of  $\alpha$  and  $\omega_\alpha$  and reduced the difference on SE estimation of these parameters with other bootstrap methods, which may indicate that the case bootstrap is more sensitive to unbalanced designs; on the other hand, stratification hardly affected the SE of  $\sigma$ .

## 5 DISCUSSION

In this paper, we evaluated different bootstrap approaches for estimating standard errors and confidence intervals of parameters in linear mixed-effects models with homoscedastic error. The proposed bootstraps take into account two levels of variability in the longitudinal data: BSV and RUV. They were also compared to the residual bootstrap, which resamples only one level of variability, and to the case bootstrap where the whole vector of observations is resampled.

Our simulations showed that bootstrapping only residuals underestimated greatly the SEs of parameters, except for  $\sigma$  and provided poor coverage rates. This finding is to be expected because the large BSV for two parameters in the evaluated designs were not taken into ac-

count. On the contrary, the case bootstrap performed well as it provided non-biased parameter estimates and SEs as well as good coverage rates for all parameters. Moreover, according to Van der Leeden et al, it makes sense to resample only the individuals and collect the related observations from the original dataset when bootstrapping cases for the repeated measures data [14, 26]. Our results support the implication that the residual variability is somewhat taken into account in this method; resampling cases preserves both the BSV and the RUV. It is in agreement with the worse performance of combining residual bootstrap with case bootstrap, in which the RUV is considered already resampled.

Another important result of this study is the good performance of bootstrapping both random effects and residuals, either in a nonparametric or in a parametric way. They worked as well as the case bootstrap. The incorporation of random effects into the classical residual bootstrap plays therefore a very important role for bootstrapping in mixed-effects models context, especially when the BSV is much higher than the RUV. This approach was proposed in various studies, such as for the resampling of multi-level data [14, 23], times series data [10] and more recently for longitudinal data [15]. It can be an alternative method to the case bootstrap when the model is correct (for nonparametric version) or both model and assumptions on distributions of parameters are correct (for parametric version). To our knowledge, there has not been any simulation study in the literature which compares this approach to the most commonly used method, the case bootstrap for mixed-effects models with longitudinal data.

Bootstrapping the raw random effects and residuals does not take into account variance underestimation, leading to shrinkage in the individual parameter estimates. To account for this issue, we employed the correction using the ratio between estimated and empirical variance-covariance matrix for the random effects and the residuals. It was shown to be an appropriate method for linear mixed-effects models because of the improvement of estimation for variance components. These ratios account for the degree of two shrinkages:  $\eta$ -shrinkage and  $\epsilon$ -shrinkage, which quantify the amount of information in the individual data about the parameters [27, 28, 29]. When the data is not informative, the random effects and residuals are shrunk toward 0 and high degree of  $\eta$ -shrinkage and  $\epsilon$ -shrinkage will be obtained. Sampling in the raw distribution will therefore underestimate the actual level of variability in the data, while correcting both empirical random effects and residuals for shrinkage restores this level. This idea of accounting for the difference between the estimated and empirical variance of residuals through an estimate of the shrinkage was proposed in bootstrapping ordinary linear models [21], and was extended for the two levels of variability found in mixed models by Wang et al [23].

The performance of different bootstrap methods was evaluated under different conditions: the rich design in which all parameters can be well estimated, the sparse design in which the variance parameters are less well estimated and the large error design in which the RUV is as important as the BSV to see whether the residual bootstraps work better. [The convergence was obtained for almost all bootstrap datasets \(90% to 100%\), which should not provide](#)

substantial bias for estimating the uncertainty of parameters. The case bootstrap and three bootstrap methods where both random effects and residuals were resampled remained the best methods and selected as bootstrap candidates for linear mixed-effects models. The purpose of this work was not to determine which was the best method overall, but to eliminate bootstrap methods that do not perform well even with linear mixed-effects models. We did note that the global residual bootstrap was slightly better than individual residual bootstrap in the sparse and large error designs, especially in estimating  $\sigma$ ; which is consistent with the non-correlated structure of residuals. In addition, the distribution of resampled residuals obtained by the global residual bootstrap was slightly closer to the original distribution of residuals. The parametric bootstrap performed best across three evaluated designs, but it requires the strongest assumptions (good prior knowledge about model structure and distributions of parameters). If the model is misspecified and the assumptions of normality of random effects and residuals are not met, this method may not be robust. In practice, one of the main reasons for using bootstrap is the uncertainty of distribution assumption, the nonparametric bootstrap may therefore preferable to the parametric bootstrap in most applications [9].

We also investigated using ML instead of REML when performing the estimation step. The difference in performance was small with less than 5%, but there was slightly more bias with ML especially for the estimation of the variance parameters, which was most apparent in the sparse design where variances were less well estimated. This means that we may expect this to be true also for non-linear mixed effect models where ML is more often used than REML for parameter estimation, although this needs to be verified in the non-linear setting. This finding should be also explored further in other settings, since the superiority of REML over ML becomes more apparent as the number of fixed effect increases, especially when the number of subjects is limited [3].

The number of bootstrap replicates ( $B$ ) depends on the estimation which we want to obtain. In simple regression models,  $B$  is recommended to be at least 100 for SE estimation and at least 1000 in the case of confidence interval estimation [30, 31]. In this simulation study, 1000 bootstrap replicates were thought to be large enough to obtain both bootstrap SE and bootstrap confidence interval for all bootstrap methods with linear mixed-effects models. Note that, in order to estimate directly the quantiles for 95% CI without interpolation,  $B=999$  should be used instead of 1000 in the future work [7]. In addition, further evaluation on choosing the number of bootstrap will be studied, especially when bootstrapping on non-linear mixed-effects models is much time-consuming and less stable.

Although in the simulation studies, the performance of the case bootstrap was similar to that of the bootstrap methods resampling both random effects and residuals, when these methods were applied to the real dataset, the case bootstrap estimated a much larger SE for both  $\alpha$  and its variability, and there was also smaller differences in the estimates of  $\sigma$  between the different bootstraps. We found a good agreement between the  $B_{P\eta,PR}$  and the asymptotic method, which were both different from the remaining methods. The difference between  $B_{P\eta,PR}$  and  $B_{\eta,GR}$  could come from different assumptions on distributions, since for the for-

mer we sample in a normal distribution while the empirical residuals used for resampling in  $B_{\eta,GR}$  were in fact not normally distributed. The difference between  $B_{\text{case,none}}$  and  $B_{\eta,GR}$  or  $B_{\eta,IR}$  might due to the unbalanced design of the real dataset in which patients have different number of observations, a structure which is preserved by the residual-bootstraps but not by the case bootstrap. Unbalanced designs, therefore, may be more challenging for the case bootstrap than for other bootstrap methods [7, 32], and stratification has been proposed to handle such situations; for example when a study includes rich and sparse data it is recommended to resample from both groups to maintain a similar structure in the bootstrap samples [33]. In this study, we tried to apply the stratified case bootstrap to the real dataset. The stratification could explain a part of the difference between the case bootstrap and other bootstrap candidates by decreasing the SEs of  $\alpha$  and  $\omega_\alpha$  to the values closer to those obtained by other methods.

In conclusion, in this study, we found that the case bootstrap performs as well as the nonparametric/parametric bootstrap of random effects and residuals in linear mixed-effects models with balanced designs and homoscedastic error. However, the residual bootstraps always generate datasets with the same design as the original data and would be expected to perform better in situations where the design is not similar for every individual. This could be the explanation for the discrepancy between the bootstraps seen in the application to the real data from the Parkinson study. We now plan to compare these methods for nonlinear mixed-effects models, addressing the issues of heteroscedasticity, the nonlinearity of model, and exploring the influence of designs with stratified bootstrap.

## Acknowledgements

The authors would like to thank the Parkinson Study Group for providing us the data from Parkinson's study as well as IFRO2 and Hervé Le Nagard for the use of the "centre de biomodélisation". We also thank the reviewer for a careful review and insightful comments that helped us to improve this paper.

During this work, Hoai-Thu Thai was supported by a research grant from Drug Disposition Department, Sanofi, Paris.

**Supplementary figures**

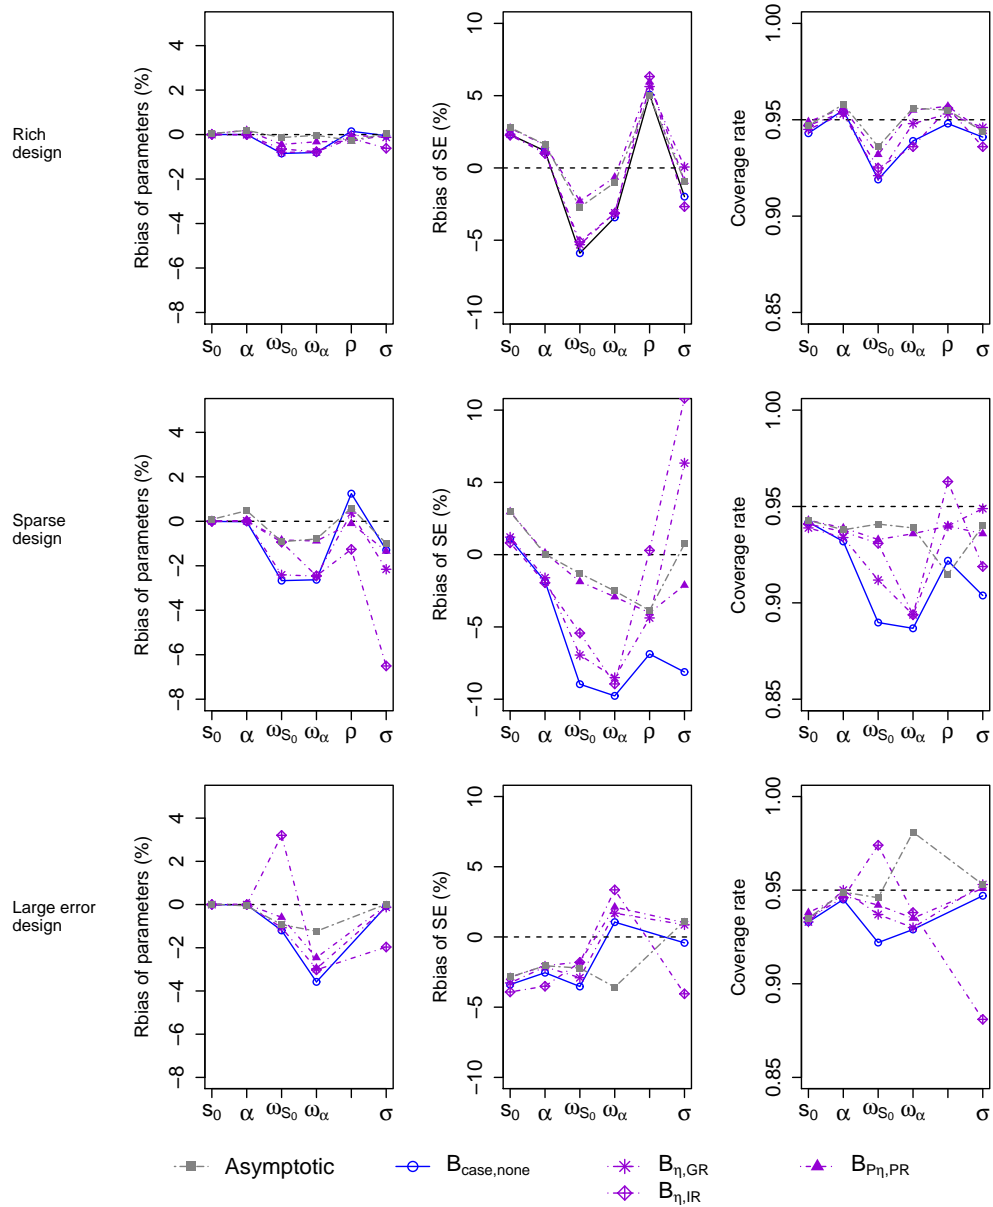

Figure S1: Relative bias of parameter estimates by REML (left), relative bias of standard errors (middle) and coverage rate of 95% CI (right), for the asymptotic method and the bootstrap candidates in the rich design ( $N=100$ ,  $n=7$ ,  $\sigma=5.86$ ) (top), the sparse design ( $N=30$ ,  $n=3$ ,  $\sigma=5.86$ ) (middle) and the large error design ( $N=100$ ,  $n=7$ ,  $\sigma=17.5$ ,  $\rho=0$ ) (bottom). The same scales were plotted to compare bootstrap methods with each other in the 3 studied designs.

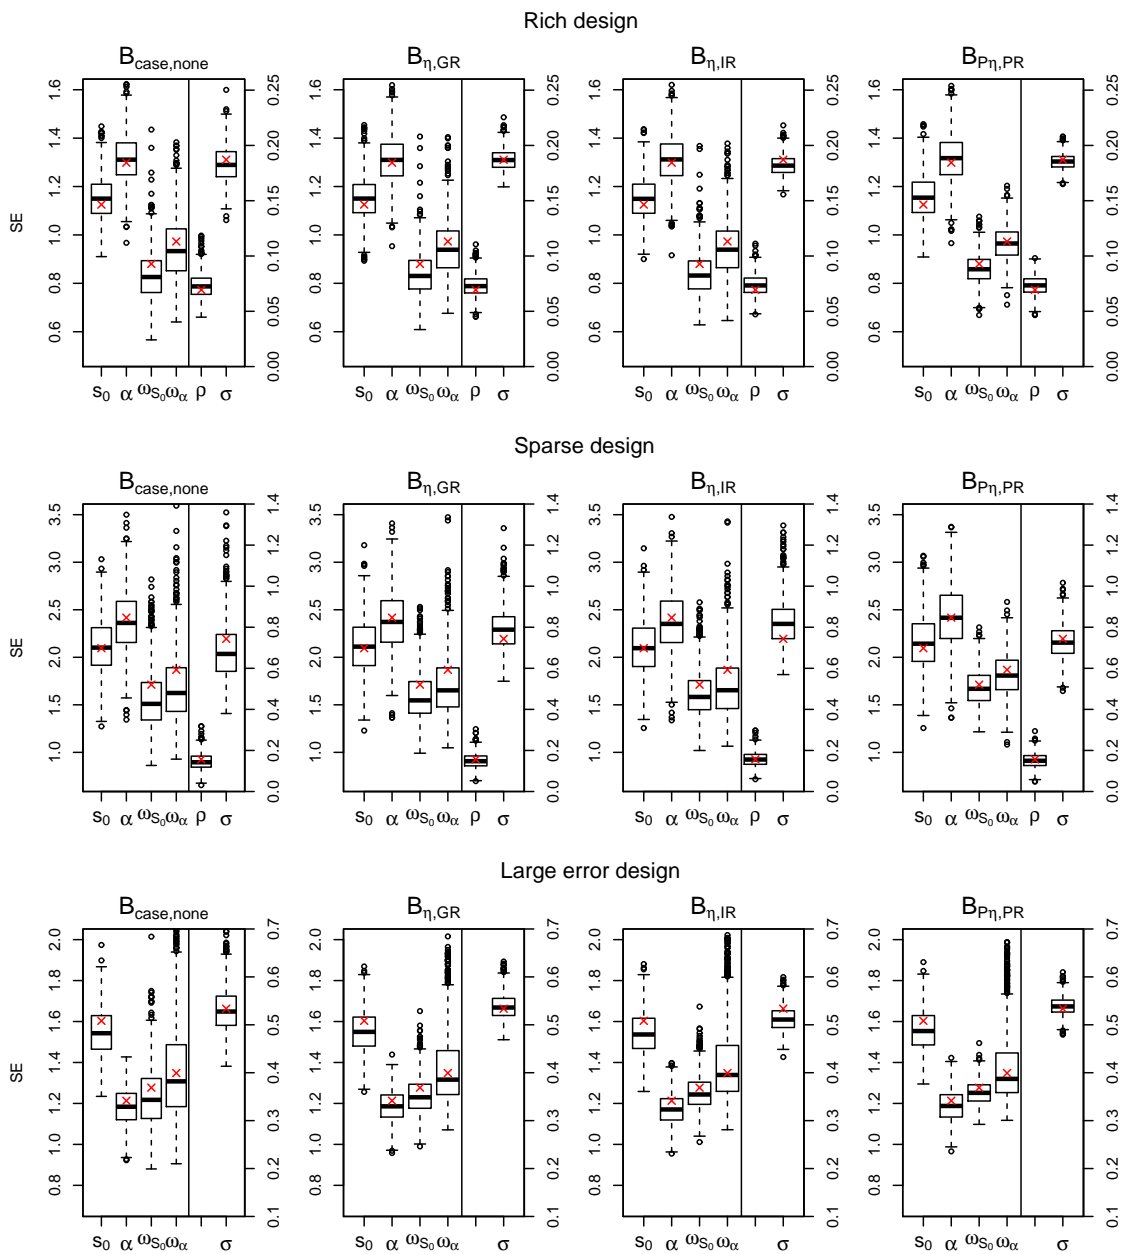

Figure S2: Boxplot of standard errors (SE) of parameters by REML obtained by the bootstrap candidates in the 3 studied designs: the rich design ( $N=100, n=7, \sigma=5.86$ ) (top), the sparse design ( $N=30, n=3, \sigma=5.86$ ) (middle) and the large error design ( $N=100, n=7, \sigma=17.5, \rho=0$ ) (bottom). A second y-axis with smaller scale was plotted for  $\rho$  and  $\sigma$  in the right side of each boxplot. The empirical values obtained by  $K=1000$  simulations were presented as red crosses.

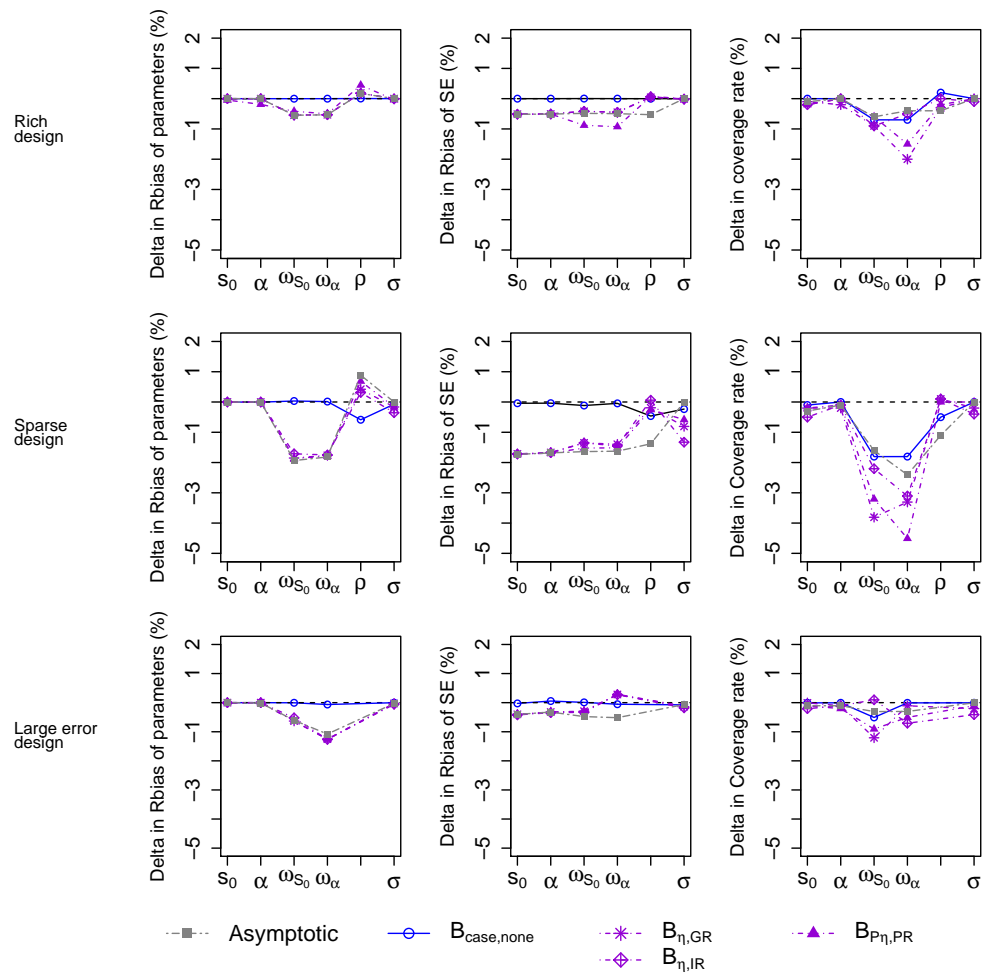

Figure S3: Difference (delta) between ML and REML (ML-REML) in relative bias of parameter estimates (left), relative bias of standard errors (middle) and coverage rate of 95% CI (right), for the asymptotic method and the bootstrap methods in the rich design ( $N=100$ ,  $n=7$ ,  $\sigma=5.86$ ) (top), the sparse design ( $N=30$ ,  $n=3$ ,  $\sigma=5.86$ ) (middle) and the large error design ( $N=100$ ,  $n=7$ ,  $\sigma=17.5$ ,  $\rho=0$ ) (bottom).
