ABSTRACT

Amyotrophic lateral sclerosis and frontotemporal dementia are two neurodegenerative diseases with currently no cure. These two diseases share a clinical continuum with overlapping genetic causes. Mutations in the *CHMP2B* gene are found in patients with ALS, FTD and ALS-FTD. To highlight deregulated mechanisms occurring in ALS-FTD linked to the *CHMP2B* gene, we performed a whole transcriptomic study on lumbar spinal cord from CHMP2B^{intron5} mice, a model that develops progressive motor alterations associated with dementia symptoms reminiscent of both ALS and FTD. To gain insight into the transcriptomic changes taking place during disease progression this study was performed at three stages: asymptomatic, symptomatic and end stage. We showed that before appearance of motor symptoms, the major disrupted mechanisms were linked with the immune system/inflammatory response and lipid metabolism. These processes were progressively replaced by alterations of neuronal electric activity as motor symptoms appeared, alterations that could lead to motor neuron dysfunction.

To investigate overlapping alterations in gene expression between two ALS-causing genes, we then compared the transcriptome of symptomatic CHMP2B^{intron5} mice with the one of symptomatic SOD1^{G86R} mice and found the same families deregulated providing further insights into common underlying dysfunction of biological pathways, disrupted or disturbed in ALS.

Altogether, this study provides a database to explore potential new candidate genes involved in the CHMP2B^{intron5}-based pathogenesis of ALS, and provides molecular clues to further understand the functional consequences that diseased neurons expressing CHMP2B mutant may have on their neighbor cells.

1. Introduction

Amyotrophic lateral sclerosis (ALS), the most common adult-onset motor neuron disease, is characterized by the degeneration of motor neurons associated with progressive muscle denervation and atrophy leading to paralysis and death usually within 2–5 years following diagnosis (Hand and Rouleau, 2002). Frontotemporal dementia (FTD) is the second most common cause of dementia in people under the age of 65 years after Alzheimer's disease (Ratnavalli et al., 2002). It mainly affects anterior temporal and/or frontal lobes of the brain, causing progressive degeneration of the frontal and temporal cortical neurons

and subsequent dementia (Pressman and Miller, 2014).

Although selective groups of neurons are primarily affected in each disease (Lillo and Hodges, 2009) increasing evidence suggests that ALS and FTD may fall into the same disease spectrum (Gascon and Gao, 2014; Ling et al., 2013). ALS and FTD share common pathophysiological features with overlapping genetic causes. Approximately 15–20% of ALS patients present with cognitive impairment reminiscent of FTD and approximately 15% of FTD patients develop ALS (Lillo and Hodges, 2009; Phukan et al., 2012). Therefore, ALS and FTD are now considered overlapping clinical syndromes with common causes. Understanding the common mechanisms and biochemical pathways driving the

neurodegenerative processes in these diseases is essential to delineate new therapeutic strategies that could be used for the diseases belonging to this continuum.

Among the genes associated with these two diseases, mutations in the *CHMP2B* (*Charged Multivesicular Body protein 2B*) gene, although rare, are found in patients with ALS (Parkinson et al., 2006; Cox et al., 2010; van Blitterswijk et al., 2012; Narain et al., 2018), FTD (Skibinski et al., 2005; van der Zee et al., 2008; Ghanim et al., 2010) and ALS-FTD (Parkinson et al., 2006) supporting the idea that ALS and FTD belong to a pathological continuum linking these two diseases.

CHMP2B is a member of the Charged Multivesicular Body Protein family. This protein contributes to the ESCRT-III complex (endosomal sorting complex required for transport III), which is involved in endocytic-lysosomal trafficking of proteins and autophagy (Urwin et al., 2009; Ghazi-Noori et al., 2012). From ongoing studies, multiple pathogenic processes have been proposed for CHMP2B mutants: disruption of *endo*-lysosomal trafficking, misregulation of transmembrane receptors, abnormal substrate degradation, down regulation of a brain-specific microRNA (Gascon et al., 2014) or abnormal dendritic spine morphology (Chassefeyre et al., 2015). However the precise mechanisms leading to disease pathogenesis and progression are still poorly understood. Indeed, ALS and FTD are complex non-cell autonomous multifactorial diseases where both neurons and glia play a critical role in disease progression (Hallmann et al., 2017; Pramatarova et al., 2001; Qian et al., 2017).

Transcriptomic analysis represents a powerful tool to analyze the complexity of disease pathobiology, to shed light on the cascade of events underlying the disease and to identify novel gene targets for therapeutic intervention. Gene expression studies performed on mutant SOD1 ALS mouse models or on tissues from sporadic ALS patients have provided invaluable insights into the molecular mechanisms involved in ALS, supporting a “multiple-hit” hypothesis of neurodegeneration. In this regard, a number of converging pathogenic mechanisms are known, including oxidative damage, defective protein misfolding, mitochondrial degeneration, impaired axonal transport, neurotrophic factor deficits, apoptosis, aberrant RNA/DNA regulation, and neuroinflammation (Krokidis and Vlamos, 2018). However, little is known about the transcriptional changes associated with *CHMP2B* mutations. To date, 12 mutations have been described in ALS (7 mutations), ALS-FTD (1 mutation) and FTD (4 mutations) patients. The *CHMP2B* mutations are disseminated throughout the sequence, irrespective of the considered pathology (Krasniak and Ahmad, 2016). In 2010, Cox and collaborators analyzed the transcriptome of spinal motor neurons from 4 ALS patients bearing different *CHMP2B* mutations (c311 C > A; c85 A > G; c618 A > C) located in exons 2, 3 and 6. They found a distinct gene expression signature with an alteration of pathways related to ER and Golgi function, vesicular transport, mTOR signaling and autophagy, MAPK and calcium signaling, axon guidance, cell cycle and apoptosis, and regulation of actin cytoskeleton. More recently Zhang and collaborators performed a RNAseq analysis on forebrain-type cortical neurons derived from human induced pluripotent stem cells obtained from patients carrying the 31449G > C mutation (Zhang et al., 2017). This mutation generates a G to C transition in the 5' acceptor splice site of exon 6, producing two aberrant transcripts: CHMP2B^{intron5} and CHMP2B^{A10} leading to a truncation of 36 amino acids at the C-terminal part of the protein. Interestingly, this deleted region contains point mutation sites found in ALS (Cox et al., 2010) and FTD (Ghanim et al., 2010) patients, suggesting a common contribution of this region to both pathologies. In addition to misregulation of genes related to endolysosomal pathway, mitochondria and oxidative stress, this study brought to light an alteration of genes involved in iron homeostasis that may trigger mitochondrial alterations, ROS production and neuronal damages. Although giving important informations about the mechanisms activated by CHMP2B mutants, these two studies present some limitations. Indeed, in both cases, the alteration of genomic profiles found are cell-type specific. Thus the obtained results can neither reflect

the global changes at a whole tissue level with complex cell-cell interactions, nor the changes of genomic profiles associated with disease progression.

We have previously shown in transgenic mice that CHMP2B^{intron5} mutant specifically expressed in neurons using the Thy1.2 promoter triggers a progressive age-dependent motor phenotype associated with behavioral changes that recapitulate ALS and FTD disorders (Vernay et al., 2016). In an attempt to better understand the mechanisms linking CHMP2B^{intron5} to ALS in this model and to investigate the impact of CHMP2B^{intron5} neuronal expression in a global context we performed a transcriptomic analysis based on RNA-sequencing on lumbar spinal cord of this transgenic CHMP2B^{intron5} mouse model. To gain access to the changes associated with disease progression, gene profiling was performed at three time-points corresponding to asymptomatic, symptomatic and end stage of the disease. In a second step, in an attempt to investigate overlapping alterations in gene expression between two ALS-causing genes, we compared the transcriptome of symptomatic CHMP2B^{intron5} mice with the one of symptomatic SOD1^{G86R} mice previously published by our laboratory (Henriques et al., 2017a, 2017b).

2. Material and methods

2.1. Ethics statement

All animal experimentations were performed in accordance with institutional and national guidelines, and approved by the local ethical committee from Strasbourg University (CREMEAS) and the ministry of higher education and research under numbers; AL/25/32/02/13, AL/51/58/02/13, APAFIS#2255, APAFIS#9494 in accordance with European regulations (Directive 2010/63/EU).

2.2. Animals

Homozygous CHMP2B^{intron5} transgenic mice overexpressing the human CHMP2B^{intron5} mutant under the Thy1.2 promoter were obtained by breeding hemizygous mice carrying 6 copies of the transgene (mixed FVB/N-DBA/2-C57BL/6 background) and were genotyped as previously described (Vernay et al., 2016). Male homozygous mice carrying 12 copies of the transgene (Tg) were used in this study and compared with control non-transgenic (nTg) littermates. Transgenic mice overexpressing murine SOD1 with the G86R mutation were genotyped as previously described (Ripps et al., 1995).

Mice were group-housed (2–5 per cage) in the animal facility of the medicine faculty of Strasbourg University, in a temperature- and humidity-controlled environment at 22 ± 1 °C under a 12-h light/dark cycle with unrestricted access to regular A04 rodent chow and water.

CHMP2B^{intron5} mice were studied at three pre-defined stages of disease progression: at 1.5 month of age, an asymptomatic (AS) stage when motor symptoms are absent; at 6 months of age corresponding to the symptomatic (S) stage of the disease when mice develop signs of hindlimb weakness; and at 10–12 months of age corresponding to the end (E) stage of the disease when mice display hindlimb paralysis or loss of the righting reflex. SOD1^{G86R} mice were studied at 90 days corresponding to the S stage of the disease when mice develop signs of hindlimb weakness. At the selected time points, mice were sacrificed by lethal injection of pentobarbital (120 mg/kg IP). Tissues were carefully dissected, snap-frozen in liquid nitrogen and stored at –80 °C or fixed by immersion in paraformaldehyde 4% in 0.1 M phosphate buffer pH 7.4 until use. Detailed protocols for histology are given in supplementary material.

2.3. RNA extraction

Total RNA was prepared following standard protocols. Briefly, each frozen sample was placed into a tube containing a 5-mm stainless steel bead. Working on ice, 1 mL Trizol reagent (Invitrogen, Groningen, The

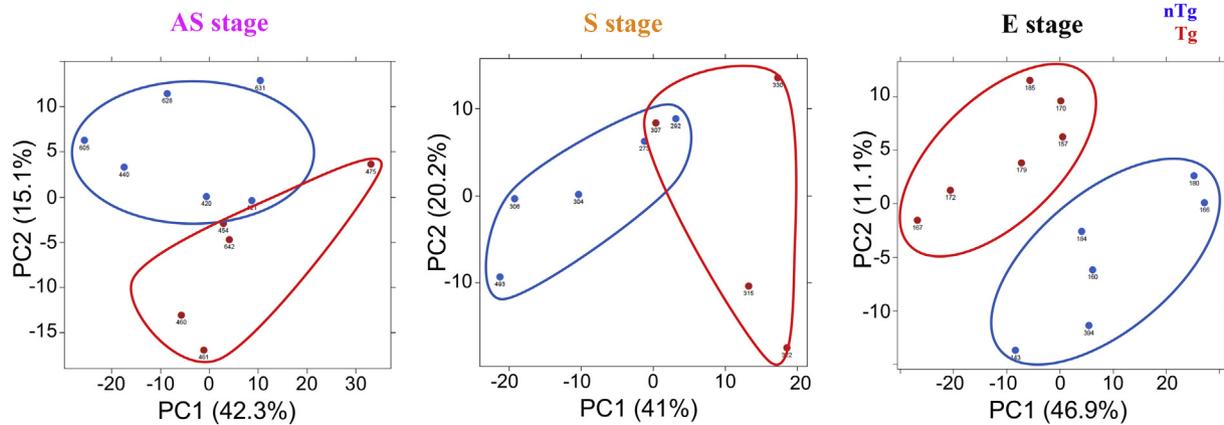

Fig. 1. Global transcriptomic signature in spinal cord. Gene expression profiles of CHMP2B^{intronic5} mice (Tg) were compared to non transgenic littermates (nTg) at three stages of the disease: asymptomatic (AS), symptomatic (S) and end (E) stages. Principal Component Analyses were computed on regularized logarithm transformed data for each stage using all genes expressed in at least one represented sample. The first factorial planes are represented on these figures and the variability explained by each axis is provided into brackets. Tg mice are plotted in red and nTg mice are plotted in blue. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Netherlands) was added, and homogenization was performed twice in a TissueLyser (Qiagen) at 30 Hz for 3 min. Samples for RNA-sequencing analysis were then processed using the RNeasy Mini Kit (Qiagen, 74,104) according to manufacturer instructions. For RT-qPCR, RNA was extracted with chloroform/isopropyl alcohol/ethanol technic. Samples were stored at -80°C until use.

2.4. RNA-sequencing

RNA-sequencing was performed by the GenomEast platform. Libraries were generated from 500 ng of total RNA using TruSeq Stranded mRNA Sample Preparation kit according to Illumina user guide (PN 15031047) with the following modifications: 2 min mRNA fragmentation and 12 cycles library PCR amplification. Libraries were then sequenced on an Illumina HiSeq 4000 system using single-end 1×50 bases. Image analysis and base calling were performed using RTA 2.7.3 and bcl2fastq 2.17.1.14. Reads were mapped onto mm10 assembly of mouse genome using Tophat v2.0.14 (Kim et al., 2013) and bowtie2 v2.1.0 aligner (Langmead and Salzberg, 2012). Quantification of gene expression was performed using HTSeq v0.6.1 (Anders et al., 2015) using gene annotations from Ensembl release 81. Normalization and differential gene expression analysis were performed using R and DESeq2 v1.6.3 Bioconductor library (Love et al., 2014). Principal Component Analysis were computed on regularized logarithm transformed data for each stage, calculated with the method proposed by Love et al. 2014, using all genes expressed in at least one represented sample. Unsupervised hierarchical clustering (Pearson correlation, average linkage) and heat maps were performed using Heatmapper (Babicki et al., 2016; <http://www.heatmapper.ca;>).

2.5. Real-time quantitative polymerase chain reaction

One microgram of total RNA was used to synthesize cDNA using Iscript reverse transcriptase (IscripTTM Reverse Transcription Supermix for RT-qPCR, Bio-Rad) as specified by the manufacturer. Quantitative PCR was performed on a CFX96 Real-time System (Bio-Rad) using iQ SYBR Green supermix (Bio-Rad). PCR was performed as follow: 95°C for 30 s, followed by 40 cycles of 4 s at 95°C and 4 s at 60°C . Three standard genes (Actin [*Acta*], Tata-box binding protein [*Tbp*] and RNA polymerase 2 subunit [*Pol II*]) were used and data were normalized with GeNorm software v3.5. Primer sequences are given in supplementary table 1.

2.6. Pathway analysis

Gene enrichment analysis was performed by using Gene Ontology and Consensus Pathway Data Base. For these analyses of the CHMP2B^{intronic5} mice, genes with an adjusted *p*-value lower than 0.05 and a fold change (FC) value < 0.67 for down-regulated or > 1.5 for up-regulated genes were selected. Pathway over-representation composed of at least 3 genes and with an adjusted *p*-value < 0.05 was considered as significantly altered.

2.7. Statistical analysis

Unless otherwise indicated, data are expressed as the mean \pm SEM. GraphPad Prism version 6.0a software was used for statistical analysis. Tests used are indicated in the legends under the figures. Differences with *p*-values < 0.05 were considered significant. The statistical significance of the overlap between the lists of significantly differentially expressed genes in CHMP2B^{intronic5} and SOD1 mice was computed using an hypergeometric test.

3. Results

3.1. Deregulated genes in the spinal cord of CHMP2B^{intronic5} mice: transcriptomic analysis discriminate between CHMP2B^{intronic5} Tg mice and nTg mice at the three stages of the disease

To gain insight into the nature and extent of gene expression changes occurring in ALS-FTD syndrome linked to CHMP2B^{intronic5} mutation in mice, the spinal cord transcriptomes of Tg and age-matched nTg mice were studied by RNA-sequencing at three stages of disease progression: AS stage (1.5 month of age, no motor symptom) S stage (6 months of age, signs of hindlimb weakness) and the E stage of the disease (10–12 months of age, hindlimb paralysis or loss of the righting reflex).

Principal component analysis (PCA) performed with the $\sim 34,000$ expressed genes for each stage showed a clear discrimination between genotypes at AS and E stages. This segregation was less pronounced at S stage probably reflecting an heterogeneity of disease progression between Tg mice (Fig. 1). Indeed, S stage represents an intermediate situation where all mice are not necessarily at the same stage of disease development even if hindlimb weakness is seen. To improve the analysis, we then selected the deregulated genes with an adjusted *p*-value < 0.05 . As shown in Table 1 the number of deregulated genes with an adjusted *p*-value < 0.05 increased with disease progression.

Table 1
Summary of the number of deregulated genes with the sequentially applied cut-off.

Cut-off stage	Number of significantly deregulated genes	
	$p < 0.05$	$p < 0.05$
		FC ≤ 0.67 or ≥ 1.5
Asymptomatic (1.5 month)	1063	281
Symptomatic (6 months)	2809	576
End-stage (10 months)	4404	348

Using this first cut-off, unsupervised hierarchical clustering showed that these differentially expressed genes segregated all the Tg mice from their nTg littermates as shown by the dendrograms in Fig. 2A. To highlight the most altered cellular processes, a fold change (FC)

value < 0.67 for down-regulated or > 1.5 for up-regulated genes and an adjusted p -value < 0.05 were used as criteria for defining a set of deregulated candidate genes in Tg when compared to nTg mice. Comparison of gene expression resulted in 281, 576 and 348 differentially regulated genes at the AS, S and E stage respectively (Table 1). Interestingly, as disease progressed, the percentage of up-regulated genes in Tg mice was decreased while the percentage of down-regulated genes was increased when compared to nTg littermates (Fig. 2B). Complete lists of genes found either up- or down-regulated in Tg when compared to nTg mice are given in supplementary tables 2–4. Among the deregulated genes identified, 49 were common to the three time points with 19 up-regulated and 30 repressed (Fig. 2C).

To ascertain RNA-sequencing results, gene expression was then assessed by RT-qPCR on an independent cohort of mice. For each stage, 10 genes were selected on the basis of their FC. Expression levels of the selected transcripts obtained by RT-qPCR were comparable with the FC

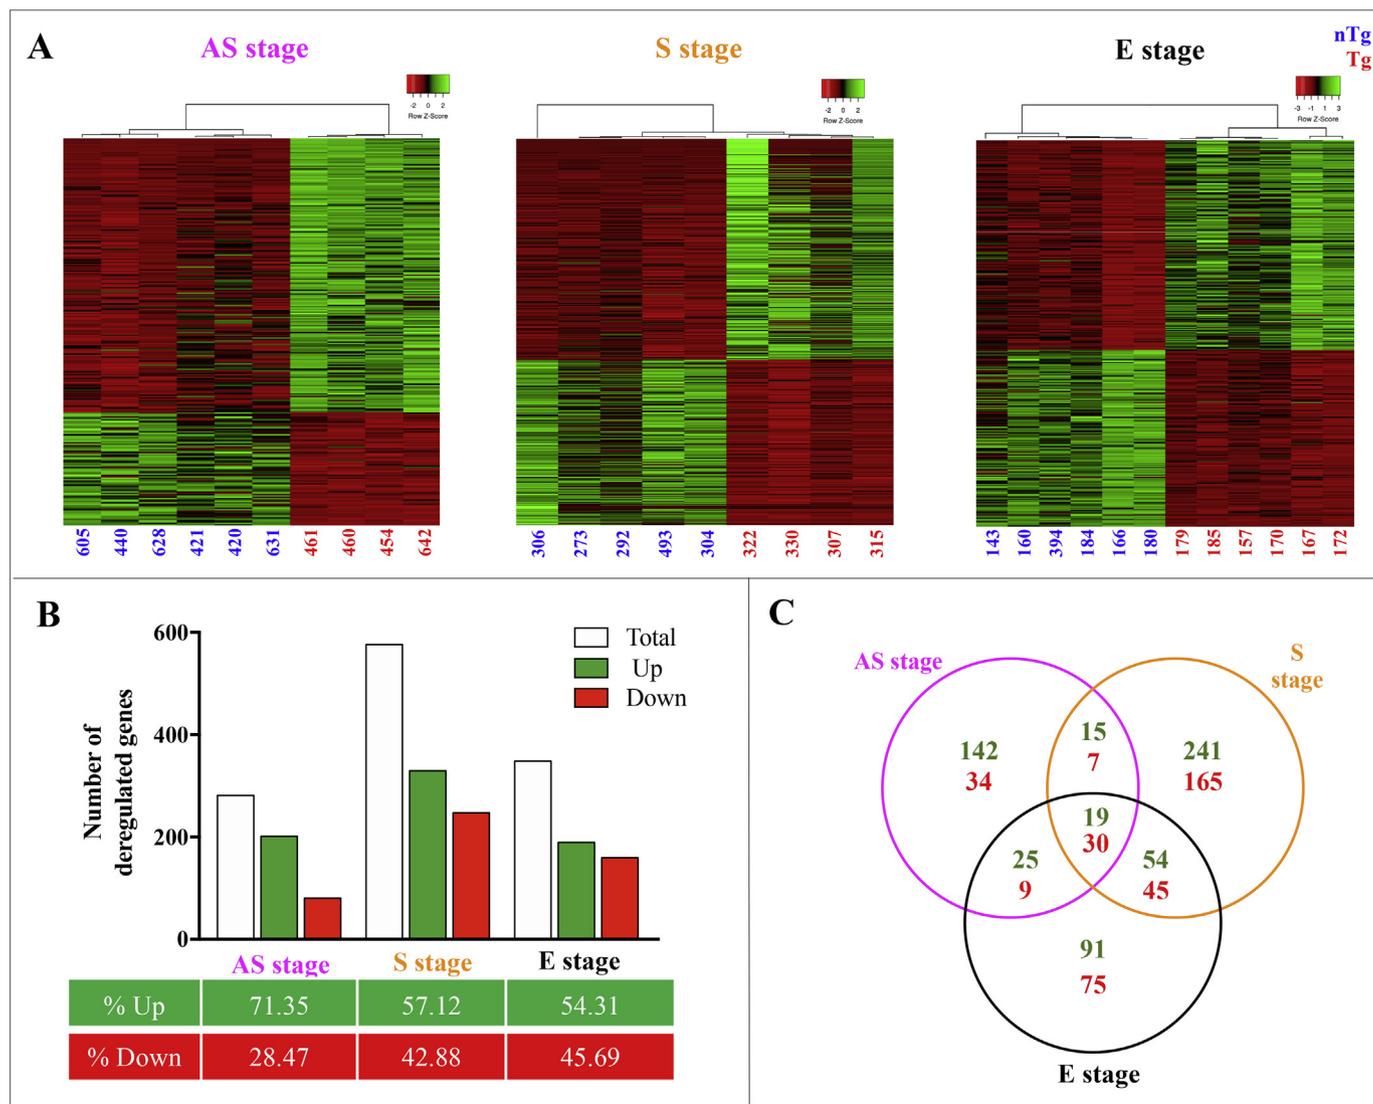

Fig. 2. Evolution of transcriptomic profile with disease progression. Genes differentially expressed with an adjusted p -value < 0.05 and a fold change < 0.67 or > 1.5 were analyzed. A: Heatmap and hierarchical clustering analysis profiles of Tg and nTg mice at the three stages studied. Scaled expression values are coloured-code according to the legend on the top right. Dendrograms depict hierarchical clustering based on differentially expressed genes and show a complete separation between genotypes at the three stages of the disease.

B. Distribution of genes with altered expression at the three stages studied in Tg vs nTg mice. White bar: total number of genes with deregulated expression, green bar: up-regulated genes, red bar: downregulated genes. The table represents the percentage of up- and down-regulated genes for each stage.

Green: up-regulated genes, Red: down-regulated genes. nTg: non transgenic mice; Tg: CHMP2B^{intron5}.

transgenic mice. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

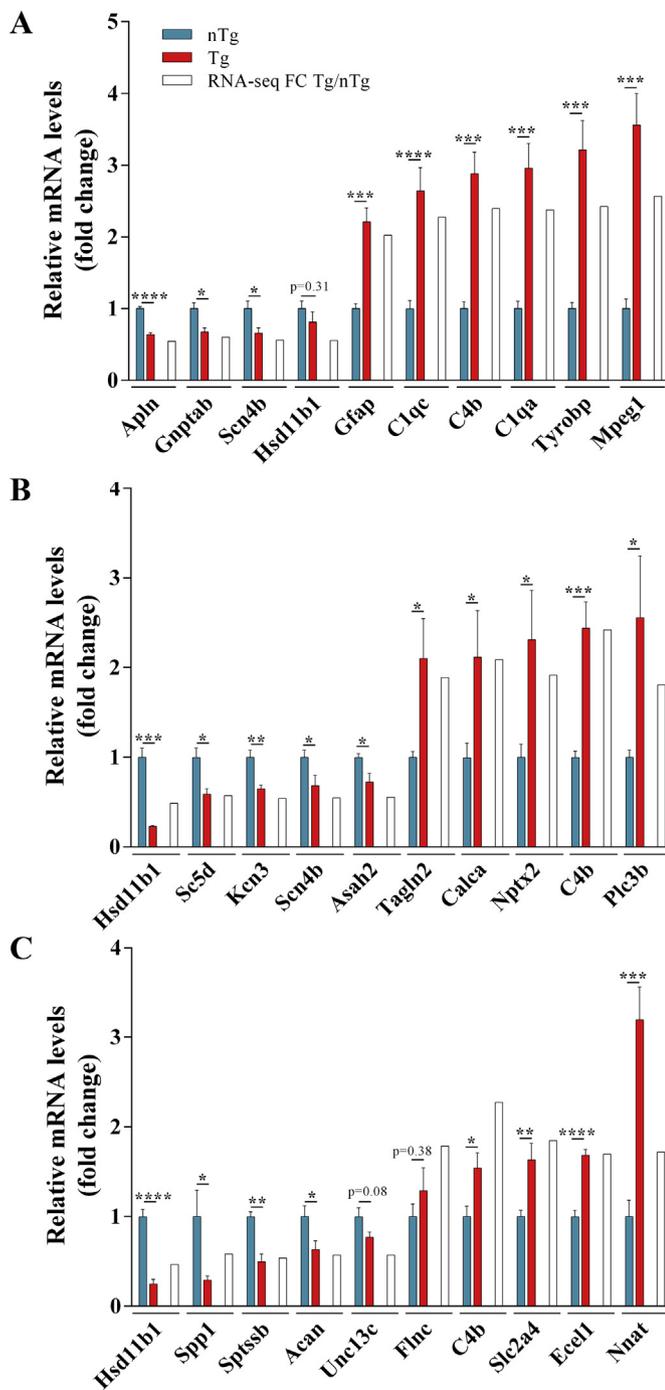

Fig. 3. Validation of RNA-seq results by RT-qPCR. For each stage, asymptomatic (A), symptomatic (B) and end stage (C) expression of 10 genes either up- or down-regulated in the RNAseq analysis was measured by RT-qPCR in an independent cohort. For the RT-qPCR graphs represent means \pm SEM. For the RNAseq graphs represent the fold change (FC). qPCR: $n = 6-7$ per genotype; RNAseq: $n = 4-6$ per genotype. * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$, **** $p < 0.0001$, Student's t -test.

found by RNA-seq analysis except for 3 genes, *Hsd11b1* at AS stage and *Unc13* ($p = 0.079$) and *Flnc* at ES stage whose regulation did not reach significance (Fig. 3).

3.2. Transcriptomic profiles evolve as disease progresses

In an attempt to identify the mechanisms altered throughout the course of the disease and the pathways with a significant number of

differentially expressed genes, gene ontology analysis was performed with significantly dysregulated genes.

At the AS stage, while no evident histological changes are found in the spinal cord (supplementary fig. 1), two major pathways emerged as over-represented: the immune system (34% of the deregulated genes; over-representation: $p_{adj} = 2.1e-14$) and the metabolism of lipids (9.6% of the deregulated genes, over-representation: $p_{adj} = 1.10e-03$). Among the 95 deregulated genes linked to the immune process 32 of them were associated with the inflammatory response (Table 2). Remarkably, except for *Cxcl9* that was down-regulated, the 31 other genes involved in inflammatory response were induced. The most up-regulated proinflammatory and chemo attractant molecules were *Ccl3*, *Ccl4* and *Ccl6* (FC > 3.8), followed by complement subunits *C1qa*, *C1qb*, *C1qc*, *C4b* (FC > 2.2) and *C3* and *C4a* (FC > 1.5) and its receptor *C3ar1* (FC = 2.01), and other receptors (*Fcer1g*, *Fcgr1*, *Csf1r*, *Ptafr* and *Tlr2*).

In addition, we showed an increase of *Trem2* (FC = 3.1) a type I transmembrane protein primarily expressed in microglia in the central nervous system and of its protein adaptor *Tyrobp* (FC = 2.42), as well as of other lectin-related inflammatory proteins such as *Lgals3* (FC = 3.39), *Clec7a* (FC = 3.06) and the integrin *Itga5* (FC = 5).

The second pathway identified as over-represented dealt with the metabolism of lipids (Table 3), a pathway known to be altered in ALS (Dupuis et al., 2008). Indeed, among the 281 deregulated genes, 27 genes belong to the lipid metabolism process with 13 genes down-regulated and 14 genes up-regulated. These deregulated genes were involved in plasma lipoprotein assembly, remodeling, and clearance, cholesterol metabolism, synthesis of very long-chain fatty acyl-CoAs and steroids metabolism (Table 3).

Six lipases were deregulated: 60 kDa lysophospholipase (*Aspg*: FC = 2.19), lipoprotein lipase (*Lpl*: FC = 1.9), phospholipase D4 (*Pld4*: FC = 1.73), phospholipase B1 (*Plb1*: FC = 1.53) endothelial lipase (*Lipg*: FC = 0.64) and phospholipase A2 (*Pla2g3*: FC = 0.58).

The two apolipoproteins *Apoc1* and *Apoe* were up-regulated with a FC of respectively 2.34 and 1.75 while cubilin (*Cubn*) a protein that mediates high density lipoproteins transport was down-regulated (FC = 0.65).

In addition, three enzymes involved in the metabolism of sphingolipids were down regulated: the serine palmitoyltransferase small subunit B (*Sptssb*: FC = 0.62), a subunit of serine palmitoyltransferase that catalyzes the first step in the biosynthesis of sphingolipids, the sphingosine-1-phosphate phosphatase 2 (*Sgpp2*: FC = 0.65) responsible of sphingosine-1-phosphate synthesis and the 2-hydroxyacylsphingosine 1-beta-galactosyltransferase (*Utg8a*: FC = 0.65) which catalyzes the synthesis of galactosylceramide from ceramide. Finally, *Hexb*, the beta subunit of hexosaminidase that converts ganglioside GM2 to GM3 was over-expressed (FC = 1.52). Four genes involved in steroid metabolism were down-regulated: the corticosteroid 11-beta-dehydrogenase isozyme 1 (*Hsd11b1*: FC = 0.55) which converts cortisone into corticosterone, 3-alpha-hydroxysteroid dehydrogenase type 1 (*Akr1c4*: FC = 0.64) that mediates neurosteroids synthesis, hydroxymethylglutaryl-CoA synthase (*Hmgcs1*: FC = 0.66) and isopentenyl-diphosphate delta-isomerase 1 (*Idi1*: FC = 0.66) that both participate to cholesterol synthesis. Two were up-regulated: testosterone 17-beta-dehydrogenase 3 (*Hsd17b3*: FC = 1.75) which converts androstenedione in testosterone and ATP-binding cassette, sub-family C (CFTR/MRP), member 3 (*Abcc3*: FC = 1.79) which is a multidrug-resistance transporter that mediates efflux of 17-beta-glucuronosyl estradiol and organic cations.

At the S stage (Table 4), when motor impairments are obvious, the mainly altered processes were related to neuronal system/activity. Indeed, 43 genes associated with this process were deregulated (7.4% of the deregulated genes; over-representation: $p_{adj} = 6.3e-6$). Most of them were related to electrical activity of the neuron including potassium and sodium channels, neurotransmitter receptors or transporters and axon guidance. Potassium channels represent the most complex class of voltage-gated ion channels from both functional and structural

standpoints. They play a crucial role in maintaining membrane potential and modulating electrical excitability in neurons. Thirteen potassium channel subunits or potassium channel-related genes were down-regulated. *Kcnh4*, *Kcnj4*, *Kcnmb1*, *Kcns1*, *Kcnc1* and *Hcn3* and *Gnb3* mRNAs were up-regulated while *Kcna1*, *Kcna2*, *Kcnc3*, *Kcng4*, *Hcn2* and *Abcc9* mRNAs were repressed. Sodium channels expression was also altered. Voltage-gated sodium channels subunits alpha *Scn9a*, *Scn10a*, *Scn11a* and nicotinic receptor subunits *Chrna6* and *Chrn3* mRNAs were up-regulated. In contrast voltage-gated sodium channel β subunit *Scn4b* and nicotinic receptor alpha2 subunit *Chrna2* mRNAs were repressed. In addition sodium-coupled neurotransmitter transporters were also identified. *Slc17a7* encoding the vesicular glutamate transporter VGLUT1 and *Slc6a12* encoding the GABA transporter GAT2 were up-regulated. At the same time, *Slc6a4* encoding the serotonin transporter SERT and *Slc6a5* encoding the glycine transporter GLYT2 were repressed. In addition, *Slc1a2* (FC = 0.72, not included in Table 3), encoding the glutamate transporter EAAT2 was also repressed but does not reach our FC threshold. Finally, mRNAs encoding GABA receptor rho2 subunit *Gabbr2* was up regulated while GABA receptor β 2 subunit *Gabbr2* and glycine receptor α 1 subunit *Gla1* were down regulated in Tg when compared to nTg mice.

At E stage deregulation of neuronal system (4.3% of the deregulated genes, over-representation: $p_{adj} = 0.038$) was still present (Table 5). However, the number of deregulated genes was decreased when compared to S stage falling from 43 to 15 genes. Potassium channels family remained the most represented family with 6 out of 15 genes identified. In addition to the neuronal system, a new pathway linked with extracellular matrix emerged (Table 6). In this pathway mRNAs encoding collagens (*Col6a*, *Col9a3*, *Col20a1* and *Col 27a1*) were up-regulated while mRNAs encoding integrins were either up- (*Itgad*, *Itgax*) or down-regulated (*Itga1*, *Itgb3*) and proteoglycans *Acan* and *Hapln* were down-regulated.

In independent control experiments, mRNA levels of neuronal markers were measured by RT-qPCR in order to determine whether the effects seen on the above mentioned neuronal genes were due to a neuronal loss. As shown on supplementary fig. 2 expression levels of the 7 different neuronal genes tested were unchanged in Tg compared to nTg mice. The absence of obvious neuronal loss was confirmed by NeuN

immunostaining.

To complete our analyses, we studied the progression of genes expression from the over-represented families. We studied the profile of each gene and classified the genes according to their expression level as compared to nTg mice, throughout the course of the disease. For each family and each stage, the number of deregulated genes and the corresponding percentage of genes either up- or down-regulated or with an unchanged expression are summarized in Table 7 and the full list of genes is given in supplementary table 5. As shown in Fig. 4, for the families that were over-represented at the AS stage, an expression pattern showing an initial up-regulation of this group of genes before returning to an expression level comparable to nTg mice largely prevailed. Indeed, 71% and 33% of the genes for the immune system/inflammation and lipid metabolism respectively showed this pattern of expression. Interestingly, in both families the percentage of over-expressed genes at AS was strongly decreased at S stage (< 10%) but increased up to 16.8% and 18.5% in both family at the E stage. In contrast, if the percentage of down-regulated genes was stable (3%) at the S and E stage for the immune system, it represented around 22% of the genes of the lipid metabolism family initially found deregulated. For the genes belonging to the neuronal system that were over-represented at S stage, the expression pattern that prevailed (~40% of the genes) showed an up-regulation limited to this stage with a normal level of expression at AS and E stages. The deregulated genes represented ~15% and ~35% of the family at the AS and E stages with a majority of repressed genes. For the two over-represented families at the E stage a common expression pattern prevailed with a normal expression level at the AS and S stages followed by an up-regulation at the E stage. These genes represented ~27% and ~46% of the deregulated genes for the neuronal system and the ECM respectively. For the neuronal system, a second pattern corresponding to a normal level of expression at the A stage followed by a down regulation at the S and E stages was seen for ~27% of the genes. The percentage of up-regulated genes increased progressively from AS (~7%) to E stage (~47%) while the percentage of repressed genes was stable at AS and S stages (~13%) and was increased by 4-folds at E stage. For the ECM family, the percentage of up-regulated genes was stable at AS and S stages (~8%) and was increased by 8-folds at E stage while the percentage of repressed genes increased

Table 3
Deregulated genes involved in the lipid metabolism at the asymptomatic stage. Spinal cords from CHMP2B^{introns5} mice were compared to non-transgenic littermates. ↑: up-regulated gene; ↓: down-regulated gene.

Gene name	Description	Fold change	adjusted p-value	Plasma lipoprotein assembly, remodeling, and clearance	Cholesterol metabolism	Synthesis of very long-chain fatty acyl-CoAs	Steroids metabolism

progressively from AS (~15%) to E stage (~38%).

Finally, in these over-represented families, 8 genes were constantly up-regulated while 12 were constantly down-regulated (supplementary table 5).

In order to further determine the genes that were constantly down-regulated during disease progression, irrespective of the over-represented families, we compared the deregulated genes at the three stages. Forty-nine genes common to AS, S and E stages were found (Table 8). Twelve genes were related to the neuronal system (*Chrna2*, *Hspb1*, *Kcnc3*, *Kcnc4*, *Nnat*, *Pdlim4*, *Scn4b*, *Slc6a5*, *Sspo*, *Steap2*, *Strip1*, *Uts2*), 5 were linked to lipid metabolism (*Apoc1*, *Gpd1*, *Hsd11b1*, *Sptssb*,

Ugt8a), 4 were linked to the immune system (*C4a*, *C4b*, *Lgals3*, *Thy1*) and 2 were related to ECM (*Acan*, *Hapln1*). In addition, a new category related to transcription became apparent with the induction of the transcriptional regulators *Atf3*, *Batf3*, *Prrx2* and *Wisp2* and the down-regulation of histone methyl transferase *Smyd1*. Interestingly all the identified genes were either up- or down-regulated over the three stages. Among the repressed genes, 11 were of unknown function.

Table 7

Table showing the percentage of genes up-regulated (FC > 1.5), non deregulated (FC [0.67–1.5]) or down-regulated (FC < 0.67) for the over-represented families at the three stages of the disease. Grey boxes indicate the stage of over-representation. For each stage, the number of deregulated genes and the total number of genes in the family are indicated into bracket.

Over-represented family	FC	AS	S	E
Immune system Inflammation	>1.5	92.6 % (88/95)	9.5 % (9/95)	16.8 % (16/95)

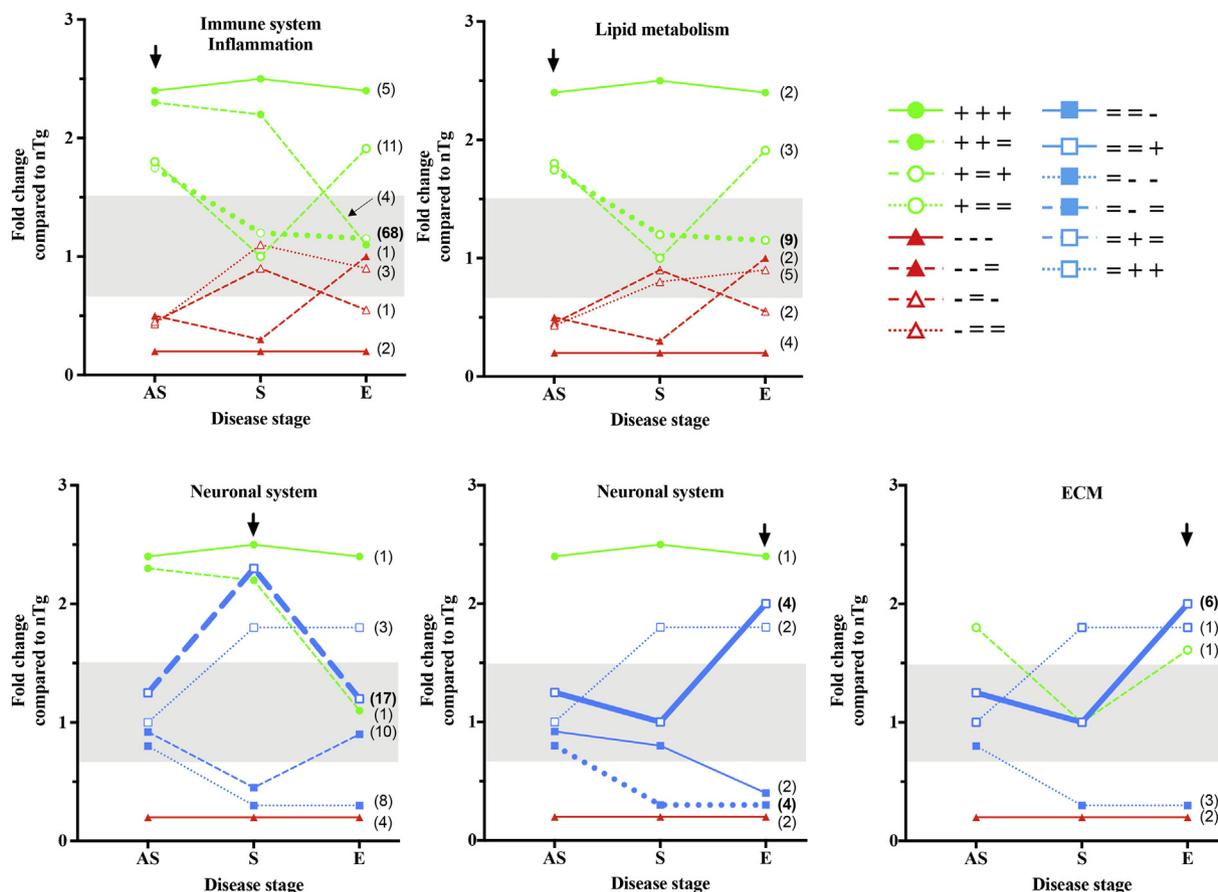

Fig. 4. Representative patterns of gene expression changes through disease progression for the genes of the over-represented families. For each family, the most represented pattern is shown in bold line. The number of genes for each pattern is indicated into brackets. Arrows indicate the stage of over-representation. Grey rectangle indicates the zone where fold change is considered non significant. AS: asymptomatic stage, S: symptomatic stage, E: end stage. +: up-regulated, =: comparable to nTg, -: downregulated.

3.3. CHMP2B^{intron5} and SOD1^{G86R} mice share common deregulated genes at symptomatic stage of the disease

In an attempt to investigate overlapping alterations in gene expression profiles and highlight pathological mechanisms common to two ALS-related mutants, we compared our results obtained on spinal cord from CHMP2B^{intron5} mice at S stage with those of transcriptomic analyses performed on spinal cord from SOD1^{G86R} mice at 90 days of age corresponding to the S stage, when mice develop signs of hindlimb weakness in this line. Using the same criteria than those used for CHMP2B^{intron5} model analysis, we found 449 deregulated genes in SOD1^{G86R} mice when compared to controls. Among them, 28 were common to both models, with 22 genes up-regulated, 3 genes down-regulated and 3 genes with opposite deregulations. The overlap between the lists of differentially expressed genes in CHMP2B^{intron5} and

SOD1^{G86R} mice was statistically significant (p -value = 2.770336e-08, hypergeometric test). We then categorized these genes and identified 7 deregulated processes (see Table 9 for details). The most represented was the immune system including inflammatory response, followed by molecules involved in transcription, lipid metabolism, neuronal system, repression of translation and cell-cell interactions. Two genes were of unknown function.

4. Discussion

This work is the first study that thoroughly characterizes the transcriptomic changes that occur throughout the course of disease progression in the spinal cord of an ALS-FTD mouse model. This model that develops characteristic features of ALS at the motor and histological levels is based on the neuronal over-expression of the CHMP2B^{intron5}

Table 8

Genes deregulated at the three stages studied in spinal cord of CHMP2B^{intron5} mice when compared to non-transgenic littermates.

mutant (Vernay et al., 2016). Using RNAseq followed by bioinformatic analysis we established that as early as 1.5 month of age, the transcriptomic profiles of CHMP2B^{intron5} Tg mice showed their own gene expression signature that differs from nTg mice. This demonstrates that transcriptomic changes, confirmed by RT-qPCR on an independent cohort, already exist several weeks before the first visible clinical motor symptoms. In this transgenic line, CHMP2B^{intron5} expression is driven by the Thy1.2 promoter, a promoter known to be neuron specific with a strong expression in motor and cortical neurons (Gordon et al., 1987). In Thy1.2-CRE transgenic mice, expression starts from E11 to E14 in the cortex depending on the transgenic line (Campsall et al., 2002). In Tg mice we found a cortical expression of the CHMP2B^{intron5} mutant concomitant with the expression of endogenous CHMP2B at the mRNA levels as early as E15 (data not shown). This early expression of the transgene concomitant with endogenous CHMP2B suggests a potential effect of the mutant protein early in the course of development as it could happen in patients carrying the mutant gene.

This transcriptomic profile of over-represented families among the deregulated genes evolves through the course of the disease with a progressive switch of deregulated pathways from immune system/inflammatory response and lipid metabolism to neuronal system and ECM when motor symptoms become visible.

4.1. Neuronal expression of CHMP2B^{intron5} triggers an initial inflammation with disruption of lipid metabolism before onset of motor symptoms

Inflammatory processes are strongly related to ALS and FTD but also to other neurodegenerative disorders such as Alzheimer's or Parkinson diseases. Their role in the development and progression of neurodegenerative diseases is however not clearly understood. Here, we report that neuronal expression of CHMP2B^{intron5} mutant triggers a strong activation of immune system associated with an activation of the inflammatory response in spinal cord before any motor symptoms. Indeed, transcripts encoding chemoattractant proteins CCL3, CCL4 and CCL6 that stimulate the recruitment of inflammatory cells (Schulthess et al., 2012) are induced together with an increase of microglial/macrophage or astrocyte markers (*Aif1/Iba1; Cx3cr1; Cd68; Cd14; Cd52; Gfap*). In addition expression of IL-1 α and TNF α receptors, which are related to the proinflammatory pathway (Tortarolo et al., 2015), and complement cascade components are also up-regulated. These data are in agreement with the data obtained in another transgenic mouse line over-expressing CHMP2B^{intron5} under the prp promoter and in human CHMP2B mutation carriers. Indeed, Isaac's group demonstrated the presence of an early microgliosis in brain of CHMP2B^{intron5} mice with an up-regulation of mRNAs encoding inflammation markers including *Irf8* and *Csf1r* two genes overexpressed in our study (Clayton et al., 2017). Interestingly, in human CHMP2B mutation carriers, it was recently shown that serum levels of CCL4 are increased throughout life (Roos et al., 2018). In sporadic ALS patients CCL3, CCL4, IL-1 α are increased in CSF while TNF α receptor levels are increased in plasma. In addition CCL6 is over-expressed in astrocytes from SOD1^{G37R} mouse

model (Sun et al., 2015) and activation of complement cascade is also observed in SOD1^{G93A} mouse model (Ferraiuolo et al., 2007) and in serum of ALS patients (Apostolski et al., 1991). However, depletion of C1q or C3, two essential proteins of complement cascade, does not increase the lifespan of SOD1^{G37R} nor delay the degeneration of motor neurons (Lobsiger et al., 2013) suggesting that complement activation is a consequence rather than a cause of disease progression. We also highlight the activation of an inflammatory pathway based on TREM2. TREM2 was previously associated with both ALS pathogenesis (Cady et al., 2014) and microglial activation (Cantoni et al., 2015) and very recently with FTD caused by CHMP2B mutants (Roos et al., 2018). TREM2 is a cell surface receptor expressed by microglia, interacting with protein tyrosine kinase binding protein (TYROBP). This apoptotic cell-detector which recognizes a variety of ligands, is able to bind Apolipoprotein E (ApoE) (Bailey et al., 2015) and to promote proinflammatory mechanisms by the induction of inflammatory players (Krasemann et al., 2017). Interestingly, using microarray analysis, Cox and collaborators found that *ApoE* is over-expressed in motoneurons of human CHMP2B mutation carriers (Cox et al., 2010). Our results show the induction of *Trem2* and its interactor *Tyrobp* associated with an induction of *ApoE* and inflammatory markers including *Clec7a*, *Lgals3*, *Gpnmb* and *Itgax*. Interestingly, *Clec7a* is also over-expressed in astrocytes of SOD1^{G93A} ALS mouse model (Baker et al., 2015) while *Itgax* and *ApoE* are increased in microglia (Chiu et al., 2013). However, the exact consequence of TREM2 pathway activation is currently still a matter of debate. Indeed, recent data suggest a rather beneficial neuroprotective role of TREM2 by interacting with TLR2 and CD14, two genes that are both shown to be induced in the present study. Thus, whether TREM2 pathway activation is beneficial or deleterious in the pathological context linked to CHMP2B^{intron5} neuronal expression remains to be elucidated.

Lipids directly contribute to cell signaling, membrane stability/fluidity and neuronal energy balance during stress. It was recently shown that hyperlipidemia is a causal risk factor in ALS patients (Bandres-Ciga et al., 2019). Some recent lipidomic studies point toward a change in lipid metabolism in ALS-FTD patients characterized by an increase of circulating triglycerides level and cholesterol/HDL ratio, and a decrease of LDL and APOC1 (Ahmed et al., 2018; Kim et al., 2018a, 2018b). However little is known about human CHMP2B mutation carriers. Here, we show for the first time that early in the course of the disease, before any motor symptoms, that expression of genes implicated in the lipid metabolism are significantly altered in CHMP2B^{intron5} Tg mice. Indeed, expression of several genes encoding proteins involved in plasma lipoprotein formation and clearance, cholesterol metabolism, synthesis of very long chain fatty acids and steroid metabolism is altered. *ApoE* expression is increased as previously found in a transcriptomic analysis of motor neurons from human CHMP2B mutation carriers (Cox et al., 2010). However, in an experimental cellular model (IPSC-derived cortical neurons expressing CHMP2B mutant) an opposite result was obtained suggesting a potential importance of culture manipulations and conditions or the limits of such models

(Zhang et al., 2017). Lipidation of APOE can be performed by ABCA1 a membrane receptor mainly found in the plasma membrane of astrocytes that mediates the efflux of cholesterol and phospholipids to lipid-poor apolipoproteins (Wahrle et al., 2004). In the present transcriptomic analysis *Abca1* expression is also found to be induced (FC = 1.41) although not reaching the chosen threshold of significance. Nevertheless, this increase of *Abca1* could favor the transport of lipids by APOE to neurons and glia. Associated with these up-regulations of lipids import factors, LPL which hydrolyzes and transports free fatty-acids to neurons and schwann cells (Eckel and Robbins, 1984; Huey et al., 1998) is also induced suggesting an increase of lipids availability for these cells. Of note, gene expression profiling and proteomic analyses reported increased levels of LPL in mutant SOD1^{G93A} mouse spinal cords. However, in our study other deregulations point toward an inhibition of lipids uptake. Indeed, APOC1, known as an APOE and LPL inhibitor (Berbee et al., 2005) is increased. APOC1 regulates activities of several proteins involved in high density lipoprotein metabolism and its over-expression provokes a hypertriglyceridemia in human and murine plasma composition through the inhibition of LPL activity. This increase of *ApoC1* is also found in the spinal cord of ALS patients, impacting the uptake of lipids by neurons and glial cells (D'Erchia et al., 2017).

The decreased expression of enzymes involved in the synthesis of cholesterol and very long chain fatty acids (*Hmgcs1*, *Idi1*, *Tecrl*, *Elovl2*) could lead to a global reduction of lipids bioavailability. *Hmgcs1* was found down regulated in a transcriptomic study performed on spinal cords from ALS patients (D'Erchia et al., 2017). We further observed a decrease of *Cubn* which is involved in the endocytosis of holoparticles of HDL (Hammad et al., 1999).

Finally, sphingolipids are involved in key pathways for ALS, such as autophagy and protein clearance, cell survival, energy metabolism, and neuroinflammation. Our analysis also identified two genes whose down-regulation would deregulate the glycosphingolipid pathway: *Ugt8a* and *Hexb*. Interestingly, similar regulations were found in SOD1^{G86R} mice, and *Ugt8a* expression level correlated with disease severity (Henriques et al., 2017a, 2017b). All these alterations in lipid metabolism may affect the cell metabolism and the organization of cellular membranes and, in turn, modify axon guidance and synaptic transmission participating to disease progression and neuronal dysfunction.

In the CHMP2B^{intron5} mice, at the early stage of the disease, down-regulation of the immune system and lipid metabolism are concomitant. Numerous data have already shown that these two processes can be linked by oxidative stress. Indeed, activated microglial cells increase ROS production (Haslund-Vinding et al., 2017; Peterson and Flood, 2012) leading to oxidation of lipids in the plasma membranes of the surrounding cells (de la Haba et al., 2013; Yang et al., 2006). This oxidation of membrane lipids promotes membrane curve disturbance and favors aggregates formation. Moreover, changes in composition of membrane lipids are also known to alter synaptic plasticity and trigger apoptosis (Ledesma et al., 2012). Cutler showed that oxidative stress leads to an increase of ceramide and cholesterol in ALS patients and that inhibition of ceramide and cholesterol synthesis protects against cell death induced by oxidative stress (Cutler et al., 2002). On the other hand, specific class of lipids such as prostaglandins or platelet activating factor (PAF) can also trigger inflammation. In our study, we observed an increased expression of *Pib1* that encodes an enzyme involved in the metabolism of glycerophosphocholine, a precursor of PAF (Edwards and Constantinescu, 2009; Marrache et al., 2002). In addition, *Ptafr*, encoding the PAF receptor expressed on cell surface of microglia (Aihara et al., 2000) is also over-expressed in our transgenic mice suggesting an activation of the PAF pathway.

Altogether, the results obtained at the asymptomatic stage suggest that activation of the immune system represents the initial step of disease onset. One possible cause could be the abnormal accumulation of protein aggregates due to neuronal expression of CHMP2B^{intron5} that are already detectable at this stage and may trigger the inflammatory response, which then could further participate to neurotoxicity and

disease progression. However, activation of immune system and inflammation is not specific to CHMP2B^{intron5} mutant and seems to be a general mechanism in ALS, irrespective of the initial cause of the disease, similar activation being also found in sporadic ALS and FTD patients (McCauley and Baloh, 2018; Prado et al., 2018; Roos et al., 2018). The hypothesis of aggregate-causing inflammation has already been proposed for other neurodegenerative diseases and will be explored in the near future in this model. At this stage, the metabolism of lipid is also impacted by CHMP2B^{intron5} neuronal expression. The emerging question is: which process impacts the other? Does the inflammatory response lead to the perturbation of lipid metabolism observed in ALS patients (Schmitt et al., 2014) or the reverse? Another hypothesis could be that proinflammation and lipid metabolism impairment are associated to generate a neurotoxic environment leading to neuronal dysfunction and neuronal death. As recalled above, oxidative stress could be the possible link between inflammation and lipid metabolism.

4.2. At the symptomatic and end stages, neuronal functions are deregulated

One of the characteristic features of ALS is the presence of muscle fasciculations. The origin of fasciculations depends on the functional state of lower motor neurons and is associated with an increase of their excitability (de Carvalho and Swash, 2017; de Carvalho et al., 2017).

A precise balance between neuronal excitation and inhibition is crucial for proper functioning of the nervous system. Disturbance of neuronal excitation-inhibition homeostasis results in severe pathological phenotypes, such as excitotoxic neurodegeneration, epilepsy, muscular spasticity, and mental retardation (Zoghbi et al., 2000). Electrical activity of the neuron and excitability are tightly link to the nature of ion channels expressed by the neuron. This homeostasis relies on the expression of ion channels, neurotransmitter receptors and transporters. So far the only study linking CHMP2B mutant to an alteration of neuronal functionality showed that mutant CHMP2B elicits a decrease in synaptic activity and suggest that the pathogenic proteins may perturb synaptic plasticity and microstructure, long before overt cell death (Belly et al., 2010). In this study, at symptomatic stage when motor symptoms are present in the CHMP2B^{intron5} mice, we highlighted a major deregulation of genes implicated in the electrical activity of the neurons (i.e. potassium and sodium channels, neurotransmitter receptors and transporters) potentially leading to a hyperexcitability of the neurons. In support of this hypothesis *Kcna1* and *Kcna2*, that encode Kv1.1 and Kv1.2 alpha subunits voltage-gated potassium channels involved in repolarization and hyperpolarization of neurons by efflux of potassium ions, are down-regulated. *Kcna1* knock-out leads to a hyperexcitability of neurons with a lower excitation threshold without any change in resting potential (Brew et al., 2003) and mice develop seizures (Rho et al., 1999). In ALS patients *Kcna1* and *Kcna2* expression is decreased and correlates with hyperexcitability (Kanai et al., 2006; Kleine et al., 2008; Vucic and Kiernan, 2006), supporting the involvement of these two channels in the disease. In addition, *Scn10a* encodes Nav1.8 alpha subunit of a voltage-gated sodium channel that supports repetitive firing in response to sustained depolarization is increased, and gain-of-function mutations of Nav1.8 produce neurons hyperexcitability suggesting that over-expression of *Scn10a* could lead to hyperexcitability (Han et al., 2016). Interestingly, *Scn11a* that encodes the Nav1.9 voltage-gated sodium channel contributing to persistent hyperalgesia following exposure to inflammatory mediators (Huang et al., 2014) is increased in our study and in the transcriptomic study performed on motor neurons from human CHMP2B mutation carriers (Cox et al., 2010). As disease progresses, down-regulation of voltage-gated potassium channels persists while deregulation of sodium channels disappears.

We also observed a deregulation of the Slc family of proteins involved in neurotransmitters re-uptake. This deregulation of the Slc family is also observed in motor neurons from human CHMP2B carriers

(Cox et al., 2010) supporting the results obtained here with our model. In particular, *Slc6a4* involved in the re-uptake of serotonin is decreased, and in the spinal cord serotonin (5-HT) increases motoneuron excitability. Interestingly, the serotonin receptor 3b *Htr3b* is increased. In contrast, *Slc6a5* encoding the glycine transporter 2 (GLYT2) is decreased. It has been shown that in spinal cord of SOD1^{G93A} ALS mice decreased GLYT2 expression is due to the degeneration of inhibitory interneurons possibly responsible for the hyperexcitability of motor neurons (Hossaini et al., 2011). Further, *Slc6a12* that codes GABA transporter involved in presynaptic GABA re-uptake is increased thereby possibly stopping GABA effect more rapidly. Moreover, *Slc17a7* that encodes the vesicular glutamate transporter 1 is increased in Cox study and in our study (Cox et al., 2010). Altogether one can hypothesize that the convergence of these deregulations may drive a strong increase in neuronal excitability possibly initiating/participating to subsequent degeneration.

Finally, we also observed altered expression of genes related to extracellular matrix. Deregulation of collagen and integrin expressing genes was also reported in the transcriptomic study performed in motor neurons from human CHMP2B carriers (Cox et al., 2010). However, the consequences of these deregulations are not known and need to be further explored.

Interestingly, part of the genes of the over-represented families at one stage are also deregulated at the other stages. In particular, for the immune system-inflammation and the lipid metabolism families, a deregulation of respectively 20% and 40% of the genes initially deregulated at the AS stage is seen suggesting an involvement of these genes in the processes activated at E stage. Understanding why these genes are deregulated at the AS and E stages could give us some clues on the role of these genes in the pathogenesis.

The comparison of the deregulated genes at the three studied stages of the disease allowed us to identify constantly deregulated genes. Among these genes 49% belong to families or pathways already found deregulated at, at least, one studied stage. Among the remaining genes, one can notice that four transcription factors are commonly up-regulated: *Atf3* whose expression is increased in response to stress, *Batf3* whose expression is involved in dendritic cell differentiation, *Wisp2* that is up-regulated in ganglioside-deficient mice and thought to have a neuroprotective function (Ohkawa et al., 2011) and *Prrx2* a member of the paired family of homeobox proteins. The role of the others deregulated genes in the pathogenesis remains to be elucidated.

Surprisingly, none of the pathways considered as responsible for the pathogenicity of CHMP2B mutants (i.e. *endo*-lysosomal pathway, autophagy) were found statistically over-represented when analyzed with the chosen threshold. This unexpected result may reflect the fact that our analysis was performed on the whole lumbar spinal cord while CHMP2B^{intron5} expression was restricted to neurons. Nonetheless, considered individually, several genes related to these pathways (i.e. Rab, Atg, or cathepsins family members), were found deregulated strengthening the validity of our approach.

4.3. Comparison of transcriptomic profiles of CHMP2B^{intron5} and SOD1^{G86R} at symptomatic stage: identification of common new genes possibly involved in pathogenesis, irrespective of the genetic cause of the disease

If half of the identified genes common to the two ALS-causing mutants have already been associated with ALS or other neurodegenerative disorders (*Anxa* (Mishra et al., 2007), *Ugt8a* (Sevastou et al., 2016; Henriques et al., 2017a, 2017b)), *Atf3* (Malaspina et al., 2010; Vluc et al., 2005), *Bcl3* (Ferry et al., 2014), *Crym* (Daoud et al., 2011; Fukada et al., 2007), *Runx1* (Patel et al., 2011), *Wisp2* (Sevastou et al., 2016), *Calca* (de la Haba et al., 2013), *Calcb*, *Cd44* (Matsumoto et al., 2012), *Clic1* (Novarino et al., 2004), *Hcar2* (Wakade et al., 2014), *Spp1* (Morisaki et al., 2016; Yamamoto et al., 2017), *Lgals3* (Yan et al., 2016), *Hspb1* (Fukada et al., 2007; Gorter et al., 2018; Ylikallio et al., 2015))

the remaining genes have not been described as modified or involved in neurodegenerative diseases. However, they are related to physiological functions (immune system, neuronal system, lipid metabolism etc....) known to be altered in neurodegenerative processes and in ALS in particular. Whether the change in expression of these genes is causative of the pathological process engaged by the two mutants or if it is a consequence has to be determined. Further work, including confirmation of changes at the protein level is now required in order to confirm whether they contribute to disease progression.

5. Conclusion

Our study is the first dynamic analysis of transcriptome in a CHMP2B^{intron5} mouse model, a model developing characteristic hallmarks of ALS/FTD. Our RNA-Seq analysis of lumbar spinal cord provides a snapshot of transcriptomic events characterizing the disease at three different time points giving us an access to the very early changes engaged before motor symptoms become apparent but also to the variations of gene expression profile when motor symptoms become detectable and then when mice are paralyzed. Our results highlight an early deregulation of immune system and lipid metabolism at asymptomatic stage although transgene expression is limited to neurons.

How mutant drives these deregulations remains an open question. Understanding the mechanisms underlying these alterations and determining whether they are protective or deleterious are of prime importance to delineate new therapeutic strategies for these diseases with not cure.

We also show that appearance of motor symptoms correlate with the detectable deregulation of genes related to neuronal system and more specifically with genes involved in ions and neurotransmitters transport. These deregulations may underlie neuronal hyperexcitability that is thought to induce neuronal degeneration in ALS.

Finally the comparison of the gene expression signature of CHMP2B^{intron5} mice with those of SOD1^{G86R} mice at the symptomatic stage provides further insights into common underlying dysfunction of biological pathways, disrupted or disturbed in ALS.

It will now be interesting to test whether the genomic changes reported here have functional consequences at the level of the cognate proteins and then will then be reflected in changes in their activity. This will be particularly interesting for lipid metabolism pathway since their modification should be reflected by circulating metabolites (either in blood or CSF) and could then certainly serve as accessible biomarker for ALS, a presently unmet medical need.

In closing, our study provides a database for neuroscientists to explore potential candidate genes involved in the CHMP2B^{intron5}-based pathogenesis of ALS, and it may provide molecular clues to further understand the functional consequences that diseased neurons expressing CHMP2B mutant may have on their neighbor cells.
